

Quasi-adiabatic Continuation for Disordered Systems: Applications to Correlations, Lieb-Schultz-Mattis, and Hall Conductance

M. B. Hastings*

Microsoft Research Station Q, CNSI Building, University of California, Santa Barbara, CA, 93106, USA

We present a possible definition of a mobility gap for a many-body quantum system, in analogy to definitions of dynamical localization for single particle systems. Using this definition, we construct “corrected” quasi-adiabatic continuation operators. We show that these operators have the same locality properties as the ordinary quasi-adiabatic continuation operators do in the case of a spectral gap, and that they approximate adiabatic evolution in the region with a mobility gap just as the ordinary operators do with a spectral gap. Further, under an appropriate definition of a unique ground state (equivalently, an absence of topological order as defined in the text), we show how to introduce virtual fluxes and prove bounds similar to those obtained on an energy for the effect of inserting 2π -flux. Armed with these results, we can directly carry over previous results proven in the case of a spectral gap. We present a statement of a higher-dimensional Lieb-Schultz-Mattis theorem for disordered systems (however, the lack of translational invariance prevents us from proving the vanishing of the gap but rather only lets us prove a weaker statement that either the gap becomes superpolynomially small or the expectation value of the flux insertion operator varies in a particular way); we present a proof of decay of correlation functions; and we present a proof of Hall conductance quantization under very mild density-of-states assumptions defined later. We also generalize these definitions to the case of a “bulk mobility gap”, in the case of a system with boundaries, and present a proof of Hall conductance quantization on an annulus under appropriate assumptions.

Further, we present a new “optimized” quasi-adiabatic continuation operator which simplifies previous estimates and tightens bounds in certain cases. This is presented in an appendix which can be read independently of the rest of the paper as it also improves estimates in the case of systems with a spectral gap. This filter function used decays in time at least as fast as $\mathcal{O}(\exp(-t^\alpha))$ for all $\alpha < 1$, a class of decay that is called “subexponential” (a more precise and tighter description of what is possible is below). Using this function it is possible to tighten recent estimates of the Hall conductance quantization for gapped systems[8] to an error which also decays subexponentially (again, more precise descriptions are below), rather than just as an exponential of a power.

INTRODUCTION

Recently, the use of Lieb-Robinson[2–4] bounds, combined with appropriately chosen filter functions has led to significant progress in proving results about quantum many-body systems. Examples include the higher-dimensional Lieb-Schultz-Mattis theorem[9], where this combination of techniques was introduced, decay of correlation functions in gapped systems[3–5, 9], an area law for entanglement entropy for arbitrary one dimensional gapped systems[10], a simpler proof of Goldstone’s theorem for gapped Hamiltonians[13], and, most recently, a proof of Hall conductance quantization for interacting electrons without averaging assumptions[8].

However, these results suffer from one major limitation: they require a spectral gap. However, in many cases we would prefer to require, instead, the weaker requirement of a *mobility gap*: a gap to propagating excitations. For non-interacting systems, the concept of localization has been around since Anderson’s early work[1]. Recently, interest has arisen in the possibility of localization in interesting systems. Interesting results include the possibility of a many-body localization transition[6], and theorems proving many-body localization for certain interacting systems, albeit in a special case that can be mapped to a non-interacting system[7]. In the single particle case, one can define localization in different ways. One way is in terms of the properties of the single particle eigenstates, while a different way is in terms of the dynamics[11]. For a many-body system, the concept of single particle eigenstates no longer makes sense. Thus, we need to seek another definition.

In this paper, we present a possible definition of the concept of a mobility gap. Further definitions are required to specify how the ground state should be distinguished from other states (definition 6 below), and to generalize these concepts to open boundary conditions with gapless edge modes, as would appear in a Hall system. Using the appropriate definitions, we show how to generalize the concept of a quasi-adiabatic continuation operator[9, 12] to this kind of system, while preserving the needed locality properties. Given these results, we then are able to directly carry over many of the results previously shown using spectral gap. Under appropriate assumptions, we prove exponential decay of correlation functions, a version of a higher-dimensional Lieb-Schultz-Mattis theorem, and Hall conductance quantization.

Our mobility gap definition describes an assumption that the propagation of low energy excitations is very slow.

This assumption is stronger than the usual Lieb-Robinson bound. Lieb-Robinson bounds hold for very general classes of Hamiltonians (essentially, any lattice Hamiltonian with short-range interactions and a bound on the interaction strength). These bounds were introduced in [2]. In [9], the idea of shifting certain terms in the equation of motion in a way that maintained the norm was introduced to show that these bounds hold in a way that is independent of the dimension of the Hilbert space on each site. In [4], a more general description on arbitrary lattices was given, albeit with dimension-dependent bounds, and in [3], the dimension-independent bounds were presented for arbitrary lattices and an extension to interactions decaying slower than exponential was given (this extension will be used in the appendix of this paper).

In this paper, we also present a more general definition of a quasi-adiabatic continuation operator, that contains the previous definitions. Further, we define an exact quasi-adiabatic continuation operator in the appendix with improved decay properties in time (exactly matching adiabatic evolution while also decaying in time as an exponential of a polynomial of the time). The use of this operator significantly simplifies the error estimates, in particular in cases where we need a Lieb-Robinson bound for quasi-adiabatic evolution. For example, it significantly tightens the error estimates in the recent proof of Hall conductance quantization. The appendix can be read separately.

DEFINITIONS OF A MOBILITY GAP

We consider lattice Hamiltonians of the following form: we assume that H is a sum of terms

$$H_0 = \sum_Z H_Z, \quad (1)$$

where each H_Z is supported on set Z , and obeys the following. First, the diameter of every set Z is at most R . Second,

$$\sup_i \sum_{Z \ni i} \|H_Z\| \leq J, \quad (2)$$

where the supremum is over sites i . We let V denote the number of sites in the system. Thus, $\|H_0\| \leq JV$. We refer to R as the “range” and J as the “interaction strength”.

We use $\text{dist}(\cdot, \cdot)$ for a metric on the lattice; we measure distances between pairs of sites, pairs of sets, or a site and a set using the same function. The distance between a pair of sets is defined to be the minimum over pairs of sites in the pair of sets of the distance between the sites, and similarly for the distance between a set and a site. We use $\text{diam}(\cdot)$ to indicate the diameter of a set. For any set A , we use $\bar{A}$ to denote the complement of A . We use L to denote various measures of the linear size of the system: for the case of a torus later, for example, we will consider an L -by- L torus so that $V = L^2$.

We use Ψ_0 to indicate the ground state of H_0 , and similarly we use $P_0 = |\Psi_0\rangle\langle\Psi_0|$ to indicate the projector onto this ground state. We use E_0 to denote the energy of state Ψ_0 . We use $\|\cdot\|$ to denote the operator norm and $\|\cdot\|_1$ to denote the trace norm and we use $|\cdot|$ to denote the l^2 norm of a vector.

We use C to refer to numeric constants of order unity. If we need multiple constants in the same expression, we use $C_1, C_2, \dots$. We use $\text{poly}(\dots)$ to refer to quantities bounded by a polynomial in their arguments. We use “computer science” big-O notation: that is, indicating that a quantity is $\mathcal{O}(x)$ indicates that it is bounded by a constant times x for sufficiently large x . We use $\exp(-\text{poly}(L))$ to indicate that a quantity is $\mathcal{O}(\exp(-L^\alpha))$, for some $\alpha > 0$. When we express bounds in term of the quantities $L, \lambda_{\min}, t_{\max}, \tau$, this is always at fixed value of the quantities $J/\gamma, R, c_{\text{loc}}, \xi$ (these quantities are defined below), and we use c to denote quantities which may depend on $J/\gamma, R, c_{\text{loc}}, \xi$. That is, if we state that a quantity is bounded by $(J/\lambda_{\min}) \exp(-cL)$, we mean that the constant c is positive but may depend on $J/\gamma, R, c_{\text{loc}}, \xi$. When we state that a quantity is “superpolynomially small”, we mean that it is superpolynomially small in L , for fixed $J/\gamma, R, c_{\text{loc}}, \xi$; in all such cases where we use the term “superpolynomially small”, we assume (and explicitly state) a polynomial dependence of quantities $\lambda_{\min}, \tau$ on L and a superpolynomially dependence of $t_{\max}$ on L .

Before the definitions, some discussion is in order regarding “filter functions”. These functions play an essential role in the application of Lieb-Robinson bounds to many-body systems. The combination of these functions with Lieb-Robinson bounds was introduced in [9]. Broadly speaking, there are many places where, for a given operator O , we would like to construct a state $\tilde{f}(H_0 - E_0)O|\Psi_0\rangle$, where $\tilde{f}(H_0 - E_0)$ is some function of the Hamiltonian H_0 . That is, if H_0 has eigenvectors Ψ_i with corresponding eigenvalues E_i , then $\tilde{f}(H_0 - E_0)$ has the same eigenvectors but has the eigenvalues $\tilde{f}(E_i - E_0)$. In many such cases, the function $\tilde{f}(\omega)$ that we would like to construct is not smooth near $\omega = 0$.

The two functions that we would most like to construct are the step function and the function $1/\omega$, which are used in proving correlation decay and in defining quasi-adiabatic continuation, respectively. If a system has an energy gap, then we can define a smooth filter function, $\tilde{f}'(\omega)$, with the property that $\tilde{f}'(\omega)$ is smooth and such that $\tilde{f}(\omega) - \tilde{f}'(\omega)$ is small for $|\omega|$ larger than the energy gap. The smoothness property is used to show that the Fourier transform of $\tilde{f}'$ is rapidly decaying in time, and hence to approximate $\tilde{f}(H_0 - E_0)O|\Psi_0\rangle = \int dt f(t) \exp(iH_0 t) O \exp(-iH_0 t) |\Psi_0\rangle$, by a local operator acting on Ψ_0 , using Lieb-Robinson bounds to show locality of $\exp(iH_0 t) O \exp(-iH_0 t)$ for fixed time. The smallness of $\tilde{f}(\omega) - \tilde{f}'(\omega)$ for ω larger than the energy gap suffices to show that $|\tilde{f}(H_0 - E_0)O|\Psi_0\rangle - \tilde{f}'(H_0 - E_0)O|\Psi_0\rangle|$ is small. There have been two main classes of filter functions considered. One can consider filter functions which decay exponentially in time at the cost of an exponentially small error in $\tilde{f}(\omega) - \tilde{f}'(\omega)$. These functions, which we will call ‘‘Gaussian filters’’ (they are not equal to Gaussians, but have similar decay properties) often give the best bounds. The other class is filter functions was first considered by Osborne in [17] as a modification of the Gaussian idea. We will call these functions ‘‘exact filters’’. Exact filters have $\tilde{f}(\omega) - \tilde{f}'(\omega)$ identically equal to zero for $|\omega|$ larger than the gap. These functions are easier to work with, but they often give bounds that decay only faster than any power (in the appendix, we present a construction of these filter functions that leads to the Fourier transform of $\tilde{f}$ decaying as an exponential of a polynomial in time, for polynomial arbitrarily close to linear, but in the main text we content ourselves with superpolynomial decay); they also make it especially easy to prove Lieb-Robinson bounds for evolution under quasi-adiabatic continuation. In this paper, we will consider many of the definitions in generality, using abstract filter functions. This will enable us to either find tighter bounds, or to simplify the proofs, depending on preference.

Using such filter functions, one can define a quasi-adiabatic continuation operator to be an operator

$$i\mathcal{D}(H_s, \partial_s H_s) = \int dt F(\gamma t) \exp(iH_s t) (\partial_s H_s) \exp(-iH_s t), \quad (3)$$

where $F(t)$ is some filter function such that its Fourier transform $\tilde{F}(\omega)$ approximates $-1/\omega$ for $|\omega| \geq 1$, $F(t)$ decays rapidly in time, and $F(t)$ is odd in time and $\tilde{F}(0) = 0$. Then, the Fourier transform of $F(\gamma t)$ approximates $-1/\omega$ for $|\omega| \geq \gamma$ and so we approximate adiabatic evolution given a spectral gap γ . Later, we modify this definition to account for a mobility gap.

First, some definitions:

Definition 1. For any set A , we define $b_l(A)$ to be the set of sites within distance l of set A .

We use a Lieb-Robinson bound in the following form:

Lemma 1. Given any operator O supported on a set A , for any l and any t with $|t| \leq l/v_{LR}$, the operator

$$O(t) \equiv \exp(iH_0 t) O \exp(-iH_0 t) \quad (4)$$

can be approximated by an operator $O_l(t)$ supported on $b_l(A)$ up to an error

$$\|O_l(t) - O(t)\| \leq \frac{v_{LR}|t|}{l} g(l) |A| \|O\|, \quad (5)$$

and also, for any operator U whose support does not intersect $b_l(A)$, we have

$$\|[O(t), U]\| \leq \frac{v_{LR}|t|}{l} g(l) |A| \|O\| \|U\|, \quad (6)$$

where $|A|$ denotes the cardinality of the set A and $g(l)$ decays faster than exponentially in l/R . The quantity v_{LR} depends on R, J , while the function g depends only on R .

Proof. This is a minor variant of Lieb-Robinson bounds proven previously. See the appendix for an example of how such bounds are proven for a more general class of Hamiltonians. $\square$

For short times, having the factor of $|t|$ in the above bound is useful, as it will help us deal with cases later that would otherwise lead to divergent integrals at short times.

Definition 2. Given any operator O and function G , we define $W_{\gamma, G}(O)$ to be the operator O filtered below energy γ by

$$W_{\gamma, G}(O) = \gamma \int dt G(\gamma t) \exp(iH_0 t) O \exp(-iH_0 t), \quad (7)$$

where the filter function $G(t)$ and its corresponding Fourier transform $\tilde{G}(\omega)$ are chosen to have the properties that $\tilde{G}(\omega)$ is close to 0 for $|\omega| \geq 1$, $\tilde{G}(\omega)$ is close to 1 for $|\omega| \leq 1/2$, and $G(t)$ is an even function of t and decays rapidly in t .

Two specific examples of such filter functions are the following. First, we can define

$$G(t) = f_q(t) = \exp(-t^2/2q)[\exp(i3t/4) - \exp(-i3t/4)]/it. \quad (8)$$

For $q \rightarrow \infty$, the Fourier transform of this is a filter onto frequencies between $-3/4$ and $+3/4$. That is, it is equal to unity for $|\omega| < 3/4$ and equal to zero for $|\omega| > 3/4$. For finite q , $f_q(t)$ and its corresponding Fourier transform $\tilde{f}_q(\omega)$ obey the following properties:

- $|\tilde{f}_q(\omega)| \leq \exp(-Cq)$ if $|\omega| \geq 1$, for some numeric constant C .
- $|\tilde{f}_q(\omega) - 1| \leq \exp(-Cq)$ if $|\omega| \leq 1/2$, for some numeric constant C .
- $|f_q(t)| \leq C \exp(-t^2/2q)$, for some numeric constant C .

This is an example of a Gaussian filter. Second, we can define an exact filter. An exact filter is a function $G(\omega) = \tilde{F}_{low}(t)$, where $\tilde{F}_{low}(t)$ is an even function, decaying faster than any power of t , with $\tilde{F}_{low}(\omega) = 1$ for $|\omega| \leq 1/2$ and $\tilde{F}_{low}(\omega) = 0$ for $|\omega| = 1$.

If $G(t)$ decays rapidly as a function of t , the operator $W_{\gamma,G}(O)$ has the following localizability property which follows from a Lieb-Robinson bound:

Lemma 2. *If O is supported on set A , then for any l , the operator $W_{\gamma,G}(O)$ can be approximated by an operator $W_{\gamma,G}^l(O)$ which is supported on $b_l(A)$ up to an error*

$$\|W_{\gamma,G}(O) - W_{\gamma,G}^l(O)\| \leq \left\{ \int_{|u| \geq l\gamma/v_{LR}} |G(u)| du + g(l)|A| \int du |G(u)| \right\} \|O\|. \quad (9)$$

Proof. Let O' be defined by

$$O' = \gamma \int_{-l/v_{LR}}^{l/v_{LR}} dt G(\gamma t) \exp(iH_0 t) O \exp(-iH_0 t). \quad (10)$$

By a triangle inequality,

$$\begin{aligned} \|O' - O\| &\leq \gamma \int_{|t| \geq l/v_{LR}} dt |G(\gamma t)| \|O\| \\ &= \int_{|u| \geq l\gamma/v_{LR}} du |G(u)| \|O\| \end{aligned} \quad (11)$$

Then, define O_l by

$$O_l = \gamma \int_{-l/v_{LR}}^{l/v_{LR}} dt G(\gamma t) O_l(t). \quad (12)$$

By a triangle inequality and the Lieb-Robinson bound,

$$\begin{aligned} \|O_l - O'\| &\leq \gamma \int_{-l/v_{LR}}^{l/v_{LR}} dt |G(\gamma t)| g(l)|A| \|O\| \\ &\leq \gamma \int dt |G(\gamma t)| g(l)|A| \|O\| \\ &\leq \int du |G(u)| g(l)|A| \|O\|. \end{aligned} \quad (13)$$

Eq. (9) follows from Eqs. (11,13) by a triangle inequality. $\square$

As a corollary of the above result, we find that

Corollary 1. *If O is supported on set A , then for any l , the operator $W_{\gamma,f_q}(O)$ can be approximated by an operator $W_{\gamma,f_q}^l(O)$ which is supported on $b_l(A)$ up to an error*

$$\|W_{\gamma,f_q}(O) - W_{\gamma,f_q}^l(O)\| \leq \left(C \frac{q}{l\gamma/v_{LR}} \exp[-(l\gamma/v_{LR})^2/2q] + C\sqrt{q}g(l)|A| \right) \|O\|. \quad (14)$$

and also

Corollary 2. *If O is supported on set A , then for any l , the operator $W_{\gamma,F_{low}}(O)$ can be approximated by an operator $W_{\gamma,F_{low}}^l(O)$ which is supported on $b_l(A)$ up to an error bounded by $|A|\|O\|$ times a function decaying faster than any power of l .*

Definition 3. *A Hamiltonian H is said to have a **mobility gap** γ and localization length ξ and localization constant c_{loc} up to time t_{max} if, for any operator O supported on set A and any filter function G , and any t with $|t| \leq t_{max}$, there exists an operator $W_{\gamma,G}^{loc}(O,t)$ with the following properties. First, for any l , $W_{\gamma,G}^{loc}(O,t)$ can be approximated by an operator supported on $b_l(A)$ up to an error in operator norm bounded by*

$$c_{loc} \exp(-l/\xi) \|W_{\gamma,G}(O)\| + \max_{|\omega| \geq \gamma} |\tilde{G}(\omega)| \|O\|. \quad (15)$$

Second, we require that the state produced by acting with $W_{\gamma,G}(O)(t) = \exp(iH_0 t) W_{\gamma,G}(O) \exp(-iH_0 t)$ on the ground state is equal to the state produced by acting with the operator $W_{\gamma,G}^{loc}(O,t)$ on the ground state, i.e.,

$$W_{\gamma,q}(O)(t) \Psi_0 = W_{\gamma,G}^{loc}(O,t) \Psi_0. \quad (16)$$

Third, we have

$$\|W_{\gamma,G}^{loc}(O,t)\| \leq \|W_{\gamma,G}(O)\|. \quad (17)$$

The above definition is our many-body version of the single particle definition of localization. It is an analogue of the definition of *dynamical localization*[11]. The second term on the right-hand side of Eq. (15) reflects the “leakage” of states above the mobility gap due to the approximate nature of the filtering.

It may happen that for a given system, there are several different choices of $\gamma, \xi, c_{loc}, t_{max}$ for which the system has a mobility gap. For example, in [7], a very strong form of many-body localization was shown: for any operator O (even without filtering), the operator $\exp(iH_0 t) O \exp(-iH_0 t)$ could be approximated by an operator on a distance l with small error for l that was only logarithmically large in the time. Hence, by taking a given ξ , for the system in [7], one can find a t_{max} that is exponentially large in ξ .

We assume that the ground state of H_0 has energy $E_0 = 0$. We define λ_{min} to be the second smallest eigenvalue of H . We will assume later only very modest requirements on λ_{min} . We will need $t_{max} \lambda_{min}$ to be large, to control errors in quasi-adiabatic continuation. We will also need a unique bulk state as defined below: to have this, it suffices, but is not necessary to have $\lambda_{min} \geq 1/\text{poly}(L)$. This is a very weak requirement; for example, in a single particle system, the eigenvalue distribution is smooth, and so λ_{min} will typically be of order $1/V$.

We now define a corrected quasi-adiabatic continuation operator using the above definitions.

Definition 4. *Given a parameter-dependent Hamiltonian, H_0 , an operator O , and functions $F(t), G$ we define the **corrected quasi-adiabatic continuation operator** at mobility scale γ and low energy cutoff $\lambda^<$ to be the operator $\mathcal{D}(H_0, O)$ defined by*

$$\begin{aligned} i\mathcal{D}(H_0, O) &= \int F(2\gamma t) \exp(iH_0 t) (O - W_{\gamma,G}(O)) \exp(-iH_0 t) dt \\ &\quad + \int F(\lambda^< t) W_{\gamma,G}^{loc}(O, t) dt, \end{aligned} \quad (18)$$

where the function $F(t)$ has the property that its Fourier transform $\tilde{F}(\omega)$ obeys

$$\tilde{F}(0) = 0, \quad (19)$$

and where F is an odd function of time so that $\mathcal{D}$ is Hermitian.

Given a parameter dependent Hamiltonian $H_s = \sum_Z H_Z(s)$, we define

$$\mathcal{D}_s = \mathcal{D}(H_s, \partial_s H_s). \quad (20)$$

We also sometimes write $\mathcal{D}_s^Z = \mathcal{D}(H_s, \partial_s H_Z(s))$, so that

$$\mathcal{D}_s = \sum_Z \mathcal{D}_s^Z. \quad (21)$$

Definition 5. For each such quasi-adiabatic continuation, we define a function $\mathcal{C}(\omega)$ by

$$\mathcal{C}(\omega) \equiv \frac{1}{\lambda^<} \tilde{F}(\omega/\lambda^<) \tilde{G}(\omega) + \frac{1}{2\gamma} \tilde{F}(\omega/2\gamma)(1 - \tilde{G}(\omega)). \quad (22)$$

The operator $\mathcal{D}$ will be used to approximate adiabatic evolution in a local way. To do this, we will require that $\mathcal{C}(\omega)$ be close to $-1/\omega$ for $|\omega| \geq \lambda^>$. See lemma (6) and lemma (7) where we will show that

$$\left| \partial_0 |\Psi_0(s)\rangle - i\mathcal{D}_\alpha(H_0, \partial_s H_s) |\Psi_0\rangle \right| \leq \|\partial_s H_s\| \max_\omega |\mathcal{C}(\omega) + 1/\omega|. \quad (23)$$

The corrected quasi-adiabatic continuation operator here differs from previous ones, such as Eq. (3), by the addition of the terms involving $W_{\gamma,q}^{loc}(\partial_s H_s)$. This will be used to account for low frequency components below the mobility gap. Our idea is as follows: for frequencies above the mobility gap, we use the large frequency to enable us to approximate the adiabatic evolution by an integral over a short-range of times, and hence with a local operator, while for frequencies below the mobility gap, we greatly increase the time scale we use to approximate adiabatic evolution, but we use the assumption of localization below the mobility gap to keep the operators local.

One example of such a function F gives a Gaussian corrected quasi-adiabatic continuation operator. In [8], the quasi-adiabatic evolution operator was defined by

$$\frac{i}{\alpha\sqrt{2\pi}} \int du \int_0^u dt \exp(iH_0 t) O \exp(-iH_0 t) \exp(-u^2/2\alpha^2), \quad (24)$$

for some parameter α , while in [9, 12] a more complicated integral was used. Eq. (24) can be re-written as

$$\int dt F(t) \exp(iH_0 t) O \exp(-iH_0 t), \quad (25)$$

where $F(t)$ is defined to be

$$\frac{i}{\alpha\sqrt{2\pi}} \int_t^\infty du \exp(-u^2/2\alpha^2), \quad (26)$$

for $t > 0$ and $F(t)$ is an odd function. We can use this function $F(t)$ in our corrected quasi-adiabatic continuation definition, using $G = f_q$ for the filter function, getting

$$|\mathcal{C}(\omega) + 1/\omega| \leq C(1/\lambda_{min}) \exp[-C(\lambda^</\lambda_{min})^2 \alpha^2] + C(1/\lambda_{min}) \exp[-Cq] + C(1/\gamma) \exp[-C\alpha^2/2], \quad (27)$$

for $|\omega| \geq \lambda_{min}$, and we have

$$|F(t)| \leq C \exp[-t^2/2\alpha^2]. \quad (28)$$

Alternatively, we can define an exact corrected quasi-adiabatic continuation operator at mobility scale γ , and **low-energy cutoff** $\lambda^<$ by a function $F(t)$ where $F(t)$ is some function which has the property that its Fourier transform, $\tilde{F}(\omega)$, is odd and infinitely differentiable and equals $-1/\omega$ for $|\omega| \geq 1$. Then, we have

$$\mathcal{C}(\omega) = -1/\omega \quad (29)$$

for $|\omega| \geq \lambda^<$. Since $\tilde{F}(\omega)$ is infinitely differentiable, $F(t)$ decays faster than any power of t .

Finally, we need one more definition[24]:

Definition 6. We say that a Hamiltonian H has an (l, τ) **unique ground state** if the following holds for all $\epsilon \geq 0$. Given any density matrix ρ such that, for all sets A with $\text{diam}(A) \leq l$ the inequality

$$\|\text{Tr}_{\bar{A}}(\rho - P_0)\|_1 \leq \epsilon \quad (30)$$

holds, then

$$\|\rho - P_0\|_1 \leq \tau \sqrt{\epsilon}. \quad (31)$$

We now show that give a bound on the smallest eigenvalue, $\lambda_{\min}$, then an (l, τ) unique ground state follows for a τ that depends on $\lambda_{\min}$.

Lemma 3. If the second smallest eigenvalue is at least $\lambda_{\min}$ for a Hamiltonian H with range R and interaction strength J , then it has an $(R, 2\sqrt{JV/\lambda_{\min}})$ unique ground state according to the above definition.

Proof. Suppose Eq. (30) holds. Note that $\text{Tr}(\rho H) = \sum_Z \text{Tr}(\rho H_Z)$. Then, since each H_Z is supported on a set of diameter R , we have that $\text{Tr}((\rho - P_0)H_Z) \leq \epsilon \|H_Z\|$. Summing over Z , $\text{Tr}(\rho H) - E_0 \leq \|H\| \leq \epsilon JV$. We now maximize the 1-norm difference between ρ and P_0 subject to this constraint on the energy difference. The maximum is obtained when $\rho = |\psi\rangle\langle\psi|$, for $\psi = \cos(\theta)\Psi_0 + \sin(\theta)\Psi_1$, with Ψ_1 being an eigenstate of H with energy $\lambda_{\min}$. Using the estimate of $\text{tr}(\rho H)$, $\sin(\theta)^2 \leq \epsilon JV/\lambda_{\min}$. In this two dimensional subspace, $\rho - P_0$ equals

$$\begin{pmatrix} -\sin(\theta)^2 & \cos(\theta)\sin(\theta) \\ \cos(\theta)\sin(\theta) & \sin(\theta)^2 \end{pmatrix}, \quad (32)$$

and $\|\rho - P_0\|_1 = 2\sqrt{\sin(\theta)^4 + \cos(\theta)^2 \sin(\theta)^2} = 2\sin(\theta) \leq 2\sqrt{\epsilon JV/\lambda_{\min}}$.

Thus, Eq. (31) follows with $\tau = 2\sqrt{JV/\lambda_{\min}}$. $\square$

One fundamental idea in [9] and [8], was to show that quasi-adiabatic evolution around certain closed paths in parameter space left the energy almost unchanged at the end of the path; then, using the existence of a spectral gap, the fact that the energy was almost unchanged was used to show that we had returned to a state close to the ground state. Here, we will use this (l, τ) unique bulk state assumption instead of a spectral gap since we may not have a spectral gap. In fact, however, since we will only need the (l, τ) assumption for $\tau \geq 1/\text{poly}(L)$, from lemma (3) it suffices to have a minimum eigenvalue $\lambda_{\min}$ which is greater than or equal to $1/\text{poly}(L)$. So, the (l, τ) unique ground state assumption follows from a very weak assumption on $\lambda_{\min}$, as claimed above.

This unique ground state assumption is physically necessary when we prove Hall conductance quantization later under a weaker assumption of a mobility gap, compared to the spectral gap assumption of [8]. On physical grounds, we need to have the (l, τ) unique ground state for the following reason: consider a fractional Hall system on a torus with multiply degenerate ground state and then a spectral gap (not just a mobility gap) to the rest of the spectrum. This system will *not* display integer Hall conductance quantization. However, it will actually show a mobility gap, up to exponentially large times t , since after filtering any operator acting on one ground state can only have matrix elements to one of the other ground states, and since the splitting between the ground states is exponentially small in system size, the filtered operator will be almost unchanging in time. Thus, we do not expect that there is any Hall conductance quantization theorem in the absence of some condition like the (l, τ) unique ground state condition.

As further justification for our (l, τ) unique ground state definition, we note that if this definition does not hold for $l = L/2 - 1$ and $\tau \ll 1$, then there exists another state ψ orthogonal to Ψ_0 with the property that, given any local operator O with support on a set of diameter less than half the system size, if the operator O is projected into the two-dimensional spanned by Ψ_0, ψ it is close to the identity operator. This is a definition of topological order (see, for example the definition of (l, ϵ) topological order in [16]). Thus, since we will only use this unique ground state definition for $l \sim \text{const.} \times L$ later, we are in fact only requiring the absence of topological order.

A further reason for introducing the unique ground state assumption is that later in the context of the Hall effect with boundaries we will need a different unique bulk state assumption, definition (10), which generalizes this unique ground state assumption.

CORRELATION DECAY

The most basic result to show using these definitions is the exponential decay of correlations in a system with an unique ground state and a mobility gap. We do all these calculations with Gaussian filter functions. This section can

be read separately from the later sections of the text, because it only relies on the assumption of a mobility gap and does not use the definitions of quasi-adiabatic continuation operators.

We begin with a lemma:

Lemma 4. *Let $P_{\gamma/2}$ denote the projector onto eigenstates with energy greater than or equal to $E_0 + \gamma/2$. Let O_A, O_B be operators supported on sets A, B with $\text{dist}(A, B) = l$. Suppose that O_B has that property that*

$$\left| (1 - P_{\gamma/2}) O_B \Psi_0 \right| \leq \delta, \quad (33)$$

for some δ . Then,

$$|\langle \Psi_0, O_A O_B \Psi_0 \rangle - \langle \Psi_0, O_A \Psi_0 \rangle \langle \Psi_0, O_B \Psi_0 \rangle| \leq C \left\{ \exp(-Cl\gamma/2v_{LR}) + \min(|A|, |B|)g(l) + \delta \right\} \|O_A\| \|O_B\|. \quad (34)$$

Proof. The proof basically follows previously proven correlation bounds[3]. Assume without loss of generality that $\langle \Psi_0, O_A \Psi_0 \rangle = \langle \Psi_0, O_B \Psi_0 \rangle = 0$. For any operator X , following [5], we define $\tilde{X}^+$ by

$$\tilde{X}^+ = \lim_{\epsilon \rightarrow 0^+} \frac{1}{2\pi} \int dt \exp(iH_0 t) X \exp(-iH_0 t) \frac{\exp[-(t\gamma/2)^2/2q]}{it + \epsilon}, \quad (35)$$

for some q which will be chosen equal to $l\gamma/2v_{LR}$ below.

The operator $\tilde{X}^+$ is equal to $X(t) = \exp(iH_0 t)$ convolved against the function $(1/2\pi)(\exp[-(t\gamma/2)^2/2q])/(it + \epsilon)$. For $q \rightarrow \infty$, the Fourier function converges to a step function, vanishing for negative ω , and unity for positive ω . For finite q , one may show that for any such operator X , we have

$$\left| P_{\gamma/2} (X - \tilde{X}^+) |\Psi_0\rangle \right| \leq C \frac{\exp(-q/2)}{\sqrt{2\pi q}} \|X\|, \quad (36)$$

as shown in [5], and also that

$$\left| \langle \Psi_0 | (X - \tilde{X}^+) P_{\gamma/2} \right| \leq C \frac{\exp(-q/2)}{\sqrt{2\pi q}} \|X\|. \quad (37)$$

Further, one may show from Eq. (33) that

$$\left| (1 - P_{\gamma/2}) (O_B |\Psi_0\rangle - \tilde{O}_B^+ |\Psi_0\rangle) \right| \leq \delta. \quad (38)$$

Thus,

$$\left| (\tilde{O}_B^+ - O_B) |\Psi_0\rangle \right| \leq C \frac{\exp(-q/2)}{\sqrt{2\pi q}} \|O_B\| + \delta. \quad (39)$$

We now estimate the commutator $[\tilde{O}_B^+, O_A]$ by the Lieb-Robinson bound and the usual trick of splitting the time integral into integrals over early times ($|t| \leq l/v_{LR}$) and the integral over late times ($|t| \geq l/v_{LR}$). By a triangle inequality

$$\begin{aligned} \|[\tilde{O}_B^+, O_A]\| &\leq \frac{1}{2\pi} \int dt \frac{\exp[-(t\gamma/2)^2/2q]}{|t|} \| [O_B(t), O_A] \| \\ &\leq \frac{1}{2\pi} \int_{|t| \geq l/v_{LR}} dt \frac{\exp[-(t\gamma/2)^2/2q]}{|t|} \| [O_B(t), O_A] \| + \frac{1}{2\pi} \int_{|t| < l/v_{LR}} dt \frac{v_{LR}}{l} |B| g(l) \| [O_B(t), O_A] \| \\ &\leq \frac{2}{2\pi} \int_{|t| \geq l/v_{LR}} dt \frac{\exp[-(t\gamma/2)^2/2q]}{|t|} \| O_B(t) \| \| O_A \| + \frac{1}{2\pi} \int_{|t| < l/v_{LR}} dt \frac{v_{LR}}{l} |B| g(l) \| [O_B(t), O_A] \| \\ &\leq C \left\{ (q^2 v_{LR}^2 / (l^2 \gamma^2)) \exp[-(l^2 \gamma^2 / 4 v_{LR}^2) / 2q] + |B| g(l) \right\} \| O_A \| \| O_B \|. \end{aligned} \quad (40)$$

Using the triangle inequality $|\langle \Psi_0, O_A O_B \Psi_0 \rangle| \leq |\langle \Psi_0, O_A (O_B - \tilde{O}_B^+) \Psi_0 \rangle| + |\langle \Psi_0, \tilde{O}_B^+ O_A \Psi_0 \rangle| + \|[\tilde{O}_B^+, O_A]\|$, choosing $q \sim l\gamma/2v_{LR}$, we find that

$$|\langle \Psi_0, O_A O_B \Psi_0 \rangle| \leq C \left\{ \frac{v_{LR}}{l\gamma} \exp(-Cl\gamma/2v_{LR}) + g(l)|B| + \delta \right\} \|O_A\| \|O_B\|. \quad (41)$$

Since $(v_{LR}/l\gamma) \exp(-Cl\gamma/2v_{LR}) \leq C \exp(-l\gamma/2v_{LR})$ for $l \geq v_{LR}/\gamma$, we have

$$|\langle \Psi_0, O_A O_B \Psi_0 \rangle| \leq C \left\{ \exp(-Cl\gamma/2v_{LR}) + g(l)|B| + \delta \right\} \|O_A\| \|O_B\|. \quad (42)$$

One can replace the $|B|$ with $|A|$ by applying the Lieb-Robinson bound to the evolution of O_A rather than O_B . $\square$

Theorem 1. Assume that H has a mobility gap γ , localization length ξ and localization constant c_{loc} up to time t_{max} . Let O_A, O_B be operators supported on sets A, B with $\text{dist}(A, B) = l$. Assume that the lowest eigenvalue of H is λ_{min} . Then,

$$|\langle \Psi_0 O_A O_B \Psi_0 \rangle| \leq \left\{ Cg(l/2)|A| + \exp(-t_{max}\lambda_{min}) + \log(2v_{LR}t_{max}/l) \left(c_{loc} \exp(-l/\xi) + C \exp(-Cl\gamma/2v_{LR}) \right) \right\} \|O_A\| \|O_B\|. \quad (43)$$

Proof. Assume, without loss of generality, that $\langle O_A \rangle = \langle O_B \rangle = 0$. Define $W_{\gamma, f_q}(O_B)$ to be the operator O_B filtered below energy γ as before. Define $Z = W_{\gamma, f_q}^{l/2}(O)$, with $q = l\gamma/2v_{LR}$. Then,

$$\langle \Psi_0, O_A O_B \Psi_0 \rangle = \langle \Psi_0, O_A (O_B - Z) \Psi_0 \rangle + \langle \Psi_0, O_A (Z - W_{\gamma, f_q}(O)) \Psi_0 \rangle + \langle \Psi_0, O_A W_{\gamma, f_q}(O) \Psi_0 \rangle. \quad (44)$$

Let $X = O_B - Z$. We have

$$\begin{aligned} \left| (1 - P_{\gamma/2}) |X \Psi_0| \right| &\leq \|W_{\gamma, f_q}^{l/2}(O_B) - W_{\gamma, f_q}(O_B)\| + \exp(-Cq) \|O_B\| \\ &\leq \left(C \frac{q}{l\gamma/2v_{LR}} \exp[-(l\gamma/2v_{LR})^2/2q] + Cg(l/2)|A| + \exp(-Cq) \right) \|O_B\|. \end{aligned} \quad (45)$$

Further, X is supported on a set which is at least distance $l/2$ from A . So, by the previous lemma,

$$\begin{aligned} |\langle \Psi_0, O_A X \Psi_0 \rangle| &\leq C \left\{ \exp(-Cl\gamma/2v_{LR}) + |A|g(l) + Cg(l/2)|A| + \exp(-Cq) \right\} \|O_A\| \|O_B\| \\ &\leq C \left\{ \exp(-Cq) + |A|g(l/2) \right\} \|O_A\| \|O_B\|. \end{aligned} \quad (46)$$

Note that if desired, the term $|A|$ in the above expression can be replaced by the cardinality of the set of sites within distance $l/2$ of B and the bound still holds.

We now consider the term $\langle \Psi_0, O_A (Z - W_{\gamma, f_q}(O)) \Psi_0 \rangle$ in Eq. (44). This is bounded by

$$\begin{aligned} &\|W_{\gamma, f_q}^{l/2}(O_B) - W_{\gamma, f_q}(O_B)\| \\ &\leq \left(C \frac{q}{l\gamma/2v_{LR}} \exp[-(l\gamma/2v_{LR})^2/2q] + Cg(l/2)|A| \right) \|O_B\|. \end{aligned} \quad (47)$$

We finally consider the term $\langle \Psi_0, O_A W_{\gamma, f_q}(O) \Psi_0 \rangle$. Define Y by

$$\begin{aligned} Y &= \int dt_{|t| \leq t_{max}} W_{\gamma, f_q}^{loc}(O, t) d(t) \\ &\quad + \int dt_{|t| \geq t_{max}} \exp(iH_0 t) W_{\gamma, f_q}(O) \exp(-iH_0 t) d(t), \end{aligned} \quad (48)$$

where the function $d(t)$ is defined by

$$d(t) = \exp[-(t\lambda_{min})^2/2q_1] \frac{\exp(i2\gamma t) - 1}{it}, \quad (49)$$

for some q_1 . This is similar to (35), but we use the filter $d(t)$. For $q_1 \rightarrow \infty$, the filter $d(t)$ has a Fourier transform equal to unity for $0 < \omega < 2\gamma$ and vanishing for $\omega < 0$ or $\omega > 2\gamma$ and so at infinite q_1 , $|W_{\gamma, f_q}(O)\Psi_0 - Y\Psi_0| \leq |P_{2\gamma} W_{\gamma, f_q}(O)\Psi_0| \leq \exp(-Cq)\|O\|$. For finite q_1 , the filter $d(t)$ approximates this filter. The filter $d(t)$ is chosen not to have a singularity at $t = 0$. So, using the assumption on λ_{min} , we find that

$$\left| W_{\gamma, f_q}(O)\Psi_0 - Y\Psi_0 \right| \leq \left(\exp(-Cq) + \frac{\exp(-q_1/2)}{\sqrt{2\pi q_1}} \right) \|O_B\|. \quad (50)$$

Similarly,

$$|\langle \Psi_0 | Y \rangle| \leq (\exp(-Cq) + \frac{\exp(-q_1/2)}{\sqrt{2\pi q_1}} \|O_B\|. \quad (51)$$

We now estimate the commutator $\|[Y, O_A]\|$. We do this using a triangle inequality. The integral over $|t| \geq t_{max}$ in (48) is bounded by $C(q_1/t_{max}\lambda_{min}) \exp[-(t_{max}\lambda_{min})^2/2q_1]$. We break the integral up of $|t| \leq t_{max}$ into two different parts. First, a part with $|t| \leq l/2v_{LR}$. Second, a part with $l/2v_{LR} \leq |t| \leq t_{max}$.

We now bound the integral over $|t| \leq l/2v_{LR}$. By the localization assumption,

$$\|[W_{\gamma, f_q}(O_B, t), O_A]\| \leq (c_{loc} \exp(-l/\xi) + C \exp(-Cq)) \|O_A\| \|O_B\|. \quad (52)$$

For $|t| \leq l/2v_{LR}$, $d(t)$ is bounded by 2γ . Thus, the integral over $|t| \leq l/2v_{LR}$ is bounded by

$$(\gamma l/v_{LR}) (c_{loc} \exp(-l/\xi) + C \exp(-Cq)) \|O_A\| \|O_B\|. \quad (53)$$

We next bound the integral over $l/2v_{LR} \leq |t| \leq t_{max}$. By the localization assumption,

$$\|[W_{\gamma, f_q}(O_B, t), O_A]\| \leq (c_{loc} \exp(-l/\xi) + C \exp(-Cq)) \|O_A\| \|O_B\|. \quad (54)$$

Thus, the integral over $l/2v_{LR} \leq |t| \leq t_{max}$ is bounded by

$$\log(2v_{LR}t_{max}/l) (c_{loc} \exp(-l/\xi) + C \exp(-Cq)) \|O_A\| \|O_B\|. \quad (55)$$

We pick $q_1 = t_{max}\lambda_{min}$. Thus by a triangle inequality,

$$|\langle \Psi_0, O_A Z \Psi_0 \rangle| \leq \left\{ Cg(l/2)|A| + \exp(-t_{max}\lambda_{min}) + \log(2v_{LR}t_{max}/l) (c_{loc} \exp(-l/\xi) + C \exp(-Cl\gamma/2v_{LR})) \right\} \|O_A\| \|O_B\|. \quad (56)$$

Thus,

$$|\langle \Psi_0 O_A O_B \Psi_0 \rangle| \leq \left\{ Cg(l/2)|A| + \exp(-t_{max}\lambda_{min}) + \log(2v_{LR}t_{max}/l) (c_{loc} \exp(-l/\xi) + C \exp(-Cl\gamma/2v_{LR})) \right\} \|O_A\| \|O_B\|. \quad (57)$$

□

PROPERTIES OF CORRECTED QUASI-ADIABATIC CONTINUATION OPERATOR

We now consider the properties of the corrected quasi-adiabatic continuation operator. There are three basic properties used previously in studying these systems. First, the quasi-adiabatic continuation operator should be local, in that it should be a sum of operators, each of which is exponentially decaying in space, in the sense that each such operator can be approximated to exponentially good accuracy by an operator with finite range. Second, the quasi-adiabatic continuation operator should approximate the exact adiabatic evolution of a state in a region in which the system has a mobility gap and a sufficiently large λ_{min} . Third, the quasi-adiabatic continuation operator should produce the correct Berry phase: that is, we should have that

$$\langle \Psi_0(s), \mathcal{D}(H_s, \partial_s H_s) \Psi_0(s) \rangle = 0, \quad (58)$$

where $\Psi_0(s)$ is the ground state of H_s . This last property follows immediately from Eq. (19) in the definition of the corrected quasi-adiabatic continuation operator and was emphasized in [13]. We now show the other two properties for Gaussian and exact filter functions.

Lemma 5. *Consider a corrected quasi-adiabatic continuation operator and a Hamiltonian with a mobility gap. Define a function $\mathcal{B}(t)$ to be the convolution of $F(\gamma t)$ with $\delta(t) - \gamma G(\gamma t)$ (here, $\delta(t)$ denotes the Dirac delta-function). Then, for any operator O with support on set A and any U with support on set B with $\text{dist}(A, B) \geq l$, then*

$$\|[\mathcal{D}(H_0, O), U]\| \leq E(l) \|O\| \|U\|, \quad (59)$$

where $E(l)$ is defined by

$$\begin{aligned} E(l) \equiv & \left\{ \max_t (|\mathcal{B}(t)|)(l/v_{LR}) |O|g(l) + \int_{|t| \geq l/v_{LR}} dt |\mathcal{B}(t)| \right\} \\ & + \left\{ t_{max} \left(c_{loc} \exp(-l/\xi) + \max_{|\omega| \geq \gamma} |\tilde{G}(\omega)| \right) + \int_{|t| \geq t_{max}} dt |F(\lambda^<t)| \right\}. \end{aligned} \quad (60)$$

and further, for any l , there exists an operator O' with support on $b_l(A)$ such that

$$\begin{aligned} & \|\mathcal{D}(H_0, O) - O'\| \\ & \leq E(l) \|O\|. \end{aligned} \quad (61)$$

Proof. We consider both terms in the definition of $\mathcal{D}$, Eq. (18), separately. For the first term, we wish to bound

$$\left\| \int dt F(t) \exp(iH_0 t) (O - W_{\gamma, G}(O)) \exp(-iH_0 t), U \right\|. \quad (62)$$

We note that the operator

$$\int dt F(t) \exp(iH_0 t) (O - W_{\gamma, G}(O)) \exp(-iH_0 t) \quad (63)$$

is equal to

$$\int dt \mathcal{B}(t) \exp(iH_0 t) O \exp(-iH_0 t), \quad (64)$$

for a function $\mathcal{B}(t)$ equal to the convolution of $F(t)$ with $\delta(t) - \gamma G(\gamma t)$.

We use a triangle inequality:

$$\begin{aligned} & \left\| \left[\int dt \mathcal{B}(t) \exp(iH_0 t) O \exp(-iH_0 t), U \right] \right\| \\ & \leq \int_{|t| \leq l/v_{LR}} dt |\mathcal{B}(t)| \left\| [\exp(iH_0 t) O \exp(-iH_0 t), U] \right\| \\ & \quad + \int_{|t| \geq l/v_{LR}} dt |\mathcal{B}(t)| \left\| [\exp(iH_0 t) O \exp(-iH_0 t), U] \right\|. \end{aligned} \quad (65)$$

The first term is bounded using the Lieb-Robinson bound by

$$\max_t (|\mathcal{B}(t)|)(l/v_{LR}) |O|g(l) \|O\| \|U\|. \quad (66)$$

The second term is bounded by

$$\int_{|t| \geq l/v_{LR}} dt |\mathcal{B}(t)| \|O\| \|U\|. \quad (67)$$

We now consider the term

$$\begin{aligned} & \left\| \left[\int dt F(\lambda^<t) W_{\gamma, G}^{loc}(O, t), U \right] \right\| \\ & \leq \int_{|t| \leq t_{max}} dt F(\lambda^<t) \left\| [W_{\gamma, G}^{loc}(O, t), U] \right\| \\ & \quad + \int_{|t| \geq t_{max}} dt F(\lambda^<t) \left\| [W_{\gamma, G}^{loc}(O, t), U] \right\|. \end{aligned} \quad (68)$$

To bound the integral over $|t| \leq t_{max}$, we use the localization assumption, to bound this by

$$t_{max} \left(c_{loc} \exp(-l/\xi) + \max_{|\omega| \geq \gamma} |\tilde{G}(\omega)| \right) \|O\| \|U\|. \quad (69)$$

The integral over $|t| \geq t_{max}$ is bounded by

$$\int_{|t| \geq t_{max}} dt |F(\lambda^< t)| \|O\| \|U\|. \quad (70)$$

Putting these results (66,67,69,70) together, Eq. (59) follows. Since Eq. (59) holds for all operators U , Eq. (61) follows: to see this, define O' to be

$$O' = \int dU U \mathcal{D}(H_0, O) U^\dagger, \quad (71)$$

where the integral is over all unitary rotations over sites not in $b_l(A)$ with the Haar measure. This trick was introduced in [16]. $\square$

Applying these results to the Gaussian corrected quasi-adiabatic continuation operator and Gaussian filter function, we have the corollary:

Corollary 3. *For a Gaussian corrected quasi-adiabatic continuation operator and a Hamiltonian with a mobility gap, the error term $E(l)$ in (60) is bounded by:*

$$\begin{aligned} & \|[\mathcal{D}(H_0, O), U]\| \\ & \leq \left\{ C(l/v_{LR})|O|g(l) + C(l\gamma/v_{LR})(l/v_{LR}) \left(\alpha^2 \exp[-C(l\gamma/v_{LR})^2/\alpha^2] + q \exp[-C(l\gamma/v_{LR})^2/q] \right) \right. \\ & \quad \left. + t_{max} \left(c_{loc} \exp(-l/\xi) + C \exp(-Cq) \right) + \frac{C t_{max} \alpha^2}{(t_{max} \lambda^<)^2} \exp[-(\lambda^< t_{max}/\alpha)^2/2] \right\} \\ & \quad \times \|O\| \|U\|. \end{aligned} \quad (72)$$

Proof. Note that $F(t)$ decays as $\exp[-t/\alpha^2]$, while $G(t)$ decays as $\exp[-Ct^2/q]$, so $\mathcal{B}(t)$ is bounded by $(\gamma t) \left(\exp[-C(\gamma t)^2/\alpha^2] + \exp[-C(\gamma t)^2/q] \right)$. Note that the function $\mathcal{B}(t)$ decays as $\exp[-C(t/\alpha)^2]$ for large t for some C . The rest follows immediately from the definitions. $\square$

Similarly, for exact corrected quasi-adiabatic continuation operators we have the corollary:

Corollary 4. *For an exact corrected quasi-adiabatic continuation operator and a Hamiltonian with a mobility gap, the error term $E(l)$ in (60) is bounded by:*

$$E(l) \leq C(l/v_{LR})|O|g(l) + \frac{1}{\gamma} Q_1(l\gamma/v_{LR}) + c_{loc} t_{max} \exp(-l/\xi) + \frac{1}{\lambda^<} Q_2(\lambda^< t_{max}), \quad (73)$$

where the functions Q_1, Q_2 decays faster than any power of their arguments.

This implies the following “superpolynomial localizability” property:

Corollary 5. *The exact corrected quasi-adiabatic continuation operator $\mathcal{D}(H_s, \partial_s H_Z(s))$ can be approximated by an operator supported on $b_l(Z)$ up to an error bounded by $|Z| \|\partial_s H_Z(s)\|$ times $1/\gamma$ times a function decaying superpolynomially in l plus $1/\lambda^<$ times a function decaying superpolynomially in $\lambda^< t_{max}$.*

We now show that this corrected quasi-adiabatic continuation operator approximates the adiabatic evolution of states for Hamiltonians with a mobility gap.

Lemma 6. *For a Gaussian corrected quasi-adiabatic continuation operator $\mathcal{D}$, and a Hamiltonian H_0 with a mobility gap, and a given $\lambda_{min} > 0$, we have*

$$\begin{aligned} & \left| \partial_s |\Psi_0(s)\rangle - i \mathcal{D}_s(H_0, \partial_s H_s) |\Psi_0\rangle \right| \\ & \leq |\tilde{F}(\omega/\lambda^<) \tilde{f}(\omega, q) + \tilde{F}(\omega/\gamma) (1 - \tilde{f}(\omega, q)) + 1/\omega| \|\partial_s H_s\| \\ & \leq C \left((1/\lambda_{min}) \exp[-C(\lambda^</\lambda_{min})^2 \alpha^2] + (1/\lambda_{min}) \exp[-Cq] + (1/\gamma) \exp[-C\alpha^2/2] \right) \|\partial_s H_s\|. \end{aligned} \quad (74)$$

where $\Psi_0(s)$ is the ground state eigenvector of H_s and the partial derivatives are taken at $s = 0$.

Proof. Let $\Psi_i(s)$ denote a complete basis of eigenstates of H_s , with corresponding eigenvalues $E_i(s)$. We have

$$\partial_s \Psi_0(s) = \sum_{i \neq 0} \frac{1}{E_0(0) - E_i(0)} \Psi_i(s) \langle \Psi_i(0), (\partial_s H_s) \Psi_0(0) \rangle, \quad (75)$$

by linear perturbation theory.

Also, by the definition of the corrected quasi-adiabatic continuation operator,

$$i\mathcal{D}_\alpha(H_0, \partial_s H_s) \Psi_0 = \sum_{i \neq 0} \mathcal{C}(E_i - E_0) \Psi_0(0) \langle \Psi_i(0), (\partial_s H_s) \Psi_0(0) \rangle, \quad (76)$$

so

$$\left| \partial_0 |\Psi_0(s)\rangle - i\mathcal{D}_\alpha(H_0, \partial_s H_s) |\Psi_0\rangle \right| \leq \|\partial_s H_s\| \max_\omega |\mathcal{C}(\omega) + 1/\omega|. \quad (77)$$

so by Eq. (27), Eq. (74) follows. $\square$

The exact version of the above lemma is much simpler:

Lemma 7. *For an exact corrected quasi-adiabatic continuation operator $\mathcal{D}$ and exact filter function F_{low} , and a Hamiltonian H_0 with a mobility gap, and a given $\lambda_{\min} \geq \lambda^<$, we have*

$$\partial_s |\Psi_0(s)\rangle = i\mathcal{D}_s(H_0, \partial_s H_s) |\Psi_0\rangle. \quad (78)$$

Proof. This proof is immediate from Eq. (29). $\square$

In some cases, the Gaussian operators above allow tighter estimates. However, from now on, for simplicity of estimates, and for the simplicity of expressing the results, we will use the exact quasi-adiabatic operators (further, using the construction in the appendix, one can see that in fact our bounds here, which will be expressed only as superpolynomial decay in L , in fact become “subexponential” decay in L , as defined in the appendix). In particular, the Gaussian operators give slightly better bounds in the Lieb-Schultz-Mattis case of the next section (we omit the results for simplicity), while the exact operators will actually lead to better bounds in the Hall conductance section.

LIEB-SCHULTZ-MATTIS-TYPE THEOREMS

We now consider applying these results to prove Lieb-Schultz-Mattis-type theorems. The ideas here will be needed for the Hall discussion later. We consider a system of linear size L . For definiteness, we consider hypercubic geometry; that is, we consider square geometry in two dimensions (L by L), cubic geometry in three dimensions, and so on.

In this section, we will assume periodic boundary conditions in one direction of the hypercube, which we call the $\hat{x}$ direction. This does not mean that we assume translation invariance in that direction as done in [9, 14]. Rather it means that our metric $\text{dist}(\cdot, \cdot)$ only measures distances between points mod(L).

The one dimensional Lieb-Schultz-Mattis theorem, as later generalized in [18], was a statement about translationally invariant one-dimensional quantum systems, with finite range and finite strength interaction, and with a conserved local charge. Having a conserved local charge means that there is some operator q_i , defined on each site i , such that $Q = \sum_i q_i$ commutes with the Hamiltonian, and such that q_i has integer eigenvalues with $\|q_i\| \leq q_{\max}$ for some given $q_{\max}$. Then, assuming that Q is not an integer multiple of L , it was proven that the gap from the ground state to the first excited state decays as $1/L$.

This was generalized to higher dimensions in [9]. The most general statement, in [15], is that if Q is not an integer multiple of L , then the gap from the ground state to the first excited state decays is bounded by $\mathcal{O}(\log(L)/L)$.

It is important to understand what being an integer multiple of L means. The work [9, 15], only required translational invariance in one direction, the $\hat{x}$ direction. However, if the system is an L -by- L' torus, and has a filling fraction $Q/V = 1/2$, then Q/L is non-integer if L' is odd. The restriction to odd width arises because we use ideas of flux insertion to construct a state which has low energy and which has a different momentum compared to the ground state, thus proving bounds on the energy gap variationally. The major improvement compared to the one-dimensional result was the ability to handle systems whose aspect ratio was of order unity.

In this section we consider disordered systems, without translation invariance. Thus, we will certainly *not* be able to prove the existence of low energy excitations in this section, because in the absence of translation invariance there

exist Hamiltonians in which Q is not an integer multiple of L but with a unique ground state and a spectral gap. Instead, what we will show is the following. We will construct a flux insertion operator which inserts 2π flux in a vertical line, and apply it to the ground state. We will show that the expectation value of the energy of the resulting state is exponentially small in L . Thus, either $\lambda_{\min}$ is exponentially small in L , or the flux insertion operator acting on the ground state produces a state which is superpolynomially close to the ground state multiplied by a phase. We then show in the latter case, where the flux insertion operator is superpolynomially close to acting on the ground state by a phase, that if Q/L is non-integer, then this phase depends in a particular way described below on which line is chosen for the flux insertion.

To define the flux insertion operator, we need to define the Hamiltonian with twisted boundary conditions. Let Q_X be defined by

$$Q_X = \sum_{i, 1 \leq x(i) \leq L/2} q_i, \quad (79)$$

where $x(i)$ is the $\hat{x}$ -coordinate of site i . That is, Q_X is the total charge in the half of the system to the left of the vertical line with $x = L/2 + 1$ and to the right of $x = 0$. Let

$$H(\theta_1, \theta_2) = \sum_Z H_Z(\theta_1, \theta_2), \quad (80)$$

where $H_Z(\theta_1, \theta_2)$ is defined as follows. If the set Z is within distance R of the vertical line $x = 0$, then $H_Z(\theta_1, \theta_2) = \exp(i\theta_1 Q_X) H_Z \exp(-i\theta_1 Q_X)$; if the set Z is within distance R of the vertical line $x = L/2$, then $H_Z(\theta_1, \theta_2) = \exp(-i\theta_2 Q_X) H_Z \exp(i\theta_2 Q_X)$; otherwise, $H_Z(\theta_1, \theta_2) = H_Z$. Note that,

$$H(\theta, -\theta) = \exp(i\theta Q_X) H \exp(-i\theta Q_X). \quad (81)$$

We define an operator $\mathcal{D}_s$ to be an exact corrected quasi-adiabatic continuation operator with $\lambda^< = \lambda_{\min}$ describing quasi-adiabatic continuation along the path from $\theta_1 = s, \theta_2 = -s$. We have that $\partial_s H(s) = \sum_Z \partial_s H_Z(s)$, and $\partial_s H_Z(s)$ is nonvanishing if Z is within distance R of the line at $x = 0$ or if Z is within distance R of the line at $x = L/2$. Let $O^{(1)}(s)$ denote the sum of terms in $\partial_s H(s)$ near the line at $x = 0$ and let $O^{(2)}(s)$ denote the sum of terms in $\partial_s H(s)$ near the line at $x = L/2$, so that $\mathcal{D}_s = \mathcal{D}(H_s, O^{(1)}(s)) + \mathcal{D}(H_s, O^{(2)}(s))$. Note that the Hamiltonians H_s are all unitarily equivalent. So, if there is a mobility gap at $s = 0$, then there is a mobility gap for all s . Under the assumption of a mobility gap, because of the superpolynomial localizability property, we can approximate the operators $\mathcal{D}(H_s, O^{(1)})$ and $\mathcal{D}(H_s, O^{(2)})$ by operators $\mathcal{D}_s^{(1)}$ and $\mathcal{D}_s^{(2)}$ supported within distance less than $L/8$ of the respective lines $x = 0$ and $x = L/2$ up to superpolynomially small error. Note that the supports of $\mathcal{D}_s^{(1,2)}$ do not overlap.

We define the flux insertion operator, W_1 , as follows. We define a unitary $U_s^{(1)}$ by

$$U_s^{(1)} = \mathcal{S}' \exp\{i \int_0^s ds' \mathcal{D}_{s'}^{(1)}\}, \quad (82)$$

where $\mathcal{S}'$ denotes that the integral is s' -ordered. Then, we set $W_1 = U_{2\pi}^{(1)}$. We define W_2 similarly: we define a unitary $U_s^{(2)}$ by

$$U_s^{(2)} = \mathcal{S}' \exp\{i \int_0^s ds' \mathcal{D}_{s'}^{(2)}\}, \quad (83)$$

and we set $W_2 = U_{2\pi}^{(2)}$.

We define

$$W = W_1 W_2. \quad (84)$$

Now, we claim that:

Lemma 8. *Assume that the system has an $(L/8, \tau)$ unique bulk state, with τ greater than or equal to $1/\text{poly}(L)$. Assume that the system has a mobility gap, with $t_{\max}$ superpolynomially large in L . Then,*

$$\min_{z_1, |z_1|=1} \left(\left| W_1 |\Psi_0\rangle - z_1 |\Psi_0\rangle \right| \right) \quad (85)$$

is bounded by J/γ times a function decaying superpolynomially in L plus $\text{poly}(L)J/\lambda^<$ times a function decaying superpolynomially in $\lambda^< t_{\max}$.

Proof. Consider any operator O supported on a set of size A at most $L/8$. If A is not within distance $L/8$ of the line $x = 0$, then

$$\langle \Psi_0 | W_1^\dagger O W_1 | \Psi_0 \rangle = \langle \Psi_0 | O | \Psi_0 \rangle, \quad (86)$$

since W_1 commutes with O and W_1 is unitary.

On the other hand, if O is within distance $L/8$ of the line $x = 0$, then

$$\begin{aligned} \langle \Psi_0 | W_1^\dagger O W_1 | \Psi_0 \rangle &= \langle \Psi_0 | W_2^\dagger W_1^\dagger O W_1 W_2 | \Psi_0 \rangle \\ &= \langle \Psi_0 | W^\dagger O W | \Psi_0 \rangle, \end{aligned} \quad (87)$$

since W_2 commutes with W_1 and O .

Define

$$U = \mathcal{S}' \exp\{i \int_0^{2\pi} ds' \mathcal{D}_{s'}\}, \quad (88)$$

along the path $s = \theta_1 = -\theta_2$. Then, the operator norm difference, $\|U - W\|$ is bounded by J/γ times a function decaying superpolynomially in L plus $\text{poly}(L)J/\lambda^<$ times a function decaying superpolynomially in $\lambda^{<t_{max}}$.

However, U is an exact quasi-adiabatic evolution, and the Hamiltonians H_s are unitarily equivalent by Eq. (81). Thus,

$$U|\Psi_0\rangle = z|\Psi_0\rangle, \quad (89)$$

for some z with $|z| = 1$. Thus, $|\langle \Psi_0 | W^\dagger O W | \Psi_0 \rangle - \langle \Psi_0 | O | \Psi_0 \rangle|$ is bounded by J/γ times a function decaying superpolynomially in L plus $\text{poly}(L)J/\lambda^<$ times a function decaying superpolynomially in $\lambda^{<t_{max}}$.

Thus, from Eqs. (86,87), for any operator O ,

$$|\langle \Psi_0 | W_1^\dagger O W_1 | \Psi_0 \rangle - \langle \Psi_0 | O | \Psi_0 \rangle| \quad (90)$$

is bounded by J/γ times a function decaying superpolynomially in L plus $\text{poly}(L)J/\lambda^<$ times a function decaying superpolynomially in $\lambda^{<t_{max}}$.

However, the lemma then follows by the assumption of $(L/8, \tau)$ unique bulk state. $\square$

We need an estimate of the Berry phase. This is similar to the ideas in[13]. Above, we claimed that

$$U|\Psi_0\rangle = z|\Psi_0\rangle, \quad (91)$$

for some z with $|z| = 1$. We now determine the value of z . We claim that

Lemma 9.

$$z = \exp(-i2\pi\overline{Q}_X), \quad (92)$$

where

$$\overline{Q}_X = \langle \Psi_0 | Q_X | \Psi_0 \rangle. \quad (93)$$

Proof. By Eq. (19),

$$\langle \Psi_s | \mathcal{D}_s | \Psi_s \rangle = 0. \quad (94)$$

However, since $\mathcal{D}_s$ an exact quasi-adiabatic evolution operator

$$i\mathcal{D}_s|\Psi_s\rangle = \partial_s\Psi_s = i(Q_X - c)\Psi_s, \quad (95)$$

for some constant c . Eq. (94) lets us determine c so that $i\mathcal{D}_s|\Psi_s\rangle = (Q_X - \overline{Q}_X)\Psi_s$. Thus, $U|\Psi_0\rangle = \exp(i2\pi Q_X) \exp(-i2\pi\overline{Q}_X)\Psi_0 = \exp(-i2\pi\overline{Q}_X)\Psi_0$. $\square$

We now consider the phase z_1 in lemma (8). Consider a flux insertion operator $W_1(x_0)$ defined precisely as the above W_1 was defined above, except for inserting the flux along the line $x = x_0$, rather than along the line $x = 0$. That is, we define

$$Q_X(x_0) = \sum_i^{1+x_0 \leq x(i) \leq L/2} q_i, \quad (96)$$

and

$$H(\theta_1, \theta_2, x_0) = \sum_Z H_Z(\theta_1, \theta_2, x_0), \quad (97)$$

where $H_Z(\theta_1, \theta_2, x_0)$ is defined as follows. If the set Z is within distance R of the vertical line $x = x_0$, then $H_Z(\theta_1, \theta_2) = \exp(i\theta_1 Q_X) H_Z \exp(-i\theta_2 Q_X)$; if the set Z is within distance R of the vertical line $x = L/2$, then $H_Z(\theta_1, \theta_2) = \exp(i\theta_2 Q_X) H_Z \exp(-i\theta_1 Q_X)$; otherwise, $H_Z(\theta_1, \theta_2) = H_Z$. Then, we can define $\mathcal{D}_s^{(1)}(x_0)$ and $W_1(x_0)$ similarly to before. Note that $W_1(0) = W_1$.

For any x , define

$$\bar{Q}_x = \sum_{i, x(i)=x} \langle \Psi_0 | q_i | \Psi_0 \rangle. \quad (98)$$

Then, we claim that

Lemma 10. *The quantity*

$$|\langle \Psi_0 | W_1(0)^\dagger W_1(1) | \Psi_0 \rangle - \exp(-i2\pi \bar{Q}_1)| \quad (99)$$

is bounded by J/γ times a function decaying superpolynomially in L plus $\text{poly}(L)J/\lambda^<$ times a function decaying superpolynomially in $\lambda^{<t_{max}}$.

Proof. We have

$$\langle \Psi_0 | W_1(0)^\dagger W_1(1) | \Psi_0 \rangle = \langle \Psi_0 | W_1(0)^\dagger W_2^\dagger W_2 W_1(1) | \Psi_0 \rangle. \quad (100)$$

By the above lemma, $W_2 W_1(0) | \Psi_0 \rangle$ is superpolynomially close to Ψ_0 times some phase $z(0)$. Similarly, one can prove $W_2 W_1(1) | \Psi_0 \rangle$ is superpolynomially close to Ψ_0 times some phase $z(1)$; note that the support of the operators $W_1(1)$ and W_2 still do not overlap. Thus,

$$\langle \Psi_0 | W_1(0)^\dagger W_1(1) | \Psi_0 \rangle \quad (101)$$

is superpolynomially close to $z(0)^\dagger z(1)$.

However, by the above lemma, $z(0)$ is superpolynomially close to $\exp(-i2\pi \sum_{x=1}^{L/2} \bar{Q}_x)$ and $z(1)$ is superpolynomially close to $\exp(-i2\pi \sum_{x=2}^{L/2} \bar{Q}_x)$. So, $z_1(0)^\dagger z_1(1)$ is superpolynomially close to $\exp(-i2\pi \bar{Q}_1)$. $\square$

Note that the choice of the line $x = 0$ was arbitrary. We can pick any line $x = x_0$ to insert flux into, and in that way define an operator $W_1(x_0)$, and then we can choose another line $x = x_0 + L/2$ to define $W_2(x_0)$ and use those two lines and repeat the above proofs, showing that the quantity

$$|\langle \Psi_0 | W_1(x_0)^\dagger W_1(x_0 + 1) | \Psi_0 \rangle - \exp(-i2\pi \bar{Q}_{x_0+1})| \quad (102)$$

is bounded by J/γ times a function decaying superpolynomially in L plus $\text{poly}(L)J/\lambda^<$ times a function. Thus, for any x_0 we have

Corollary 6. *Assume that the system has an $(L/8, \tau)$ unique bulk state, with τ greater than or equal to $1/\text{poly}(L)$. Assume that the system has a mobility gap with t_{max} superpolynomially large in L . Then,*

$$\min_{z_1, |z_1|=1} \left(||W_1(x_0) | \Psi_0 \rangle - z_1 | \Psi_0 \rangle || \right) \quad (103)$$

is bounded by J/γ times a function decaying superpolynomially in L plus $\text{poly}(L)J/\lambda^<$ times a function decaying superpolynomially in $\lambda^<t_{max}$ and also

$$\langle \Psi_0 | W_1(x_0) | \Psi_0 \rangle \quad (104)$$

is superpolynomially close to

$$z \exp(-i2\pi \sum_{x=0}^{x_0} \overline{Q}_x), \quad (105)$$

for some z which is independent of x_0 .

Thus, unless $\overline{Q}_x$ is an integer for all x , we have defined a flux operator which has an expectation value which depends on the particular line x_0 we choose. If we considered the case of a translation invariant system, this would be a contradiction, and would prove that there is not a mobility gap and a unique ground state (this is how the proof of the higher-dimensional Lieb-Schultz-Mattis theorem goes). In this case, we simply identify that there is a position-dependent expectation value of a flux insertion operator.

LIEB-ROBINSON BOUNDS FOR QUASI-ADIABATIC CONTINUATION

The previous section relied on the fact that quasi-adiabatic evolution can be approximated by a sum of local operators, and hence the evolution $\mathcal{D}$ could be approximated to superpolynomial accuracy by a sum of $\mathcal{D}^{(1)} + \mathcal{D}^{(2)}$. We now want to consider a stronger property. Suppose we have an operator, such as $\mathcal{D}$ which can be approximated by a sum of local operators. For example, suppose $\mathcal{D}$ can be approximated to superpolynomial accuracy, in l , by a sum of operators $\mathcal{D}^Z$ supported on sets Z of diameter at most l . Then, if we had an the additional bound on $\|\mathcal{D}^Z\|$, then we would have a Lieb-Robinson bound for the unitary evolution

$$U_s = \mathcal{S}' \exp\{i \int_0^s ds' \mathcal{D}_{s'}\}. \quad (106)$$

In the next two sections, on Hall conductance, we will rely on an assumption of a Lieb-Robinson bound for the quasi-adiabatic evolution operator. This bound is fairly immediate to prove if we consider the slightly simpler case of a mobility gap rather than a spectral gap. For example, consider the operator defined in Eq. (3). For simplicity, we can use an exact quasi-adiabatic evolution operator. Then, we have a bound on the operator $\mathcal{D}(H_s, \partial_s H_Z(s))$ bounded in norm by a constant times $(1/\gamma)\|\partial_s H_Z(s)\|$, and the operator also decays superpolynomially in space. Hence, we have a Lieb-Robinson bound (see the appendix for more discussion of this case).

However, in the case of a corrected quasi-adiabatic continuation operator, we also have to worry about the contribution from states below the mobility gap. In this case, the contribution of these states, the term $\int F(\lambda^<t) W_{\gamma,G}^{loc}(O, t) dt$ in the corrected quasi-adiabatic evolution operator, is local as in lemma (5), but the bound on the norm is quite weak. In particular, the norm may scale with $1/\lambda^<$, and hence may scale polynomially with L . This makes it difficult (perhaps impossible) to directly prove the Lieb-Robinson bound for corrected quasi-adiabatic evolution directly from the assumption of a mobility gap, so we will need one additional assumption.

In this section, we will define the property of a Lieb-Robinson bound for corrected quasi-adiabatic evolution that we need in the next two sections. We also present one simple assumption on the local density of states under which this Lieb-Robinson bound can be derived. Then, the results in the next two sections will depend either on the assumption of the Lieb-Robinson bound for corrected quasi-adiabatic evolution, or on the (fairly mild) assumption on the density of states.

We will consider parameter-dependent Hamiltonians in the next two sections where flux is inserted along lines. We will consider, however, more lines than in the previous section. In the case of a torus, we will have two lines describing flux inserted in one direction (the “horizontal” direction of the torus) and two other lines describing flux inserted in the other direction (the “vertical” direction of the torus). The reason we have two lines in each direction is similar to the case in the above section: we use the fact that if we insert opposite flux on two different lines then the Hamiltonian is only changed by a unitary transformation. The reason we need two different directions is that the Hall conductance is equal to the curvature when transported around an infinitesimal loop in flux space.

We will need the following Lieb-Robinson bound:

Definition 7. Consider a particular parameter dependent Hamiltonian H_s . Consider the quasi-adiabatic evolution operator, $\mathcal{D}_s$ at $s = 0$, and corresponding unitary U_s . Then, we say that two sets A, B are **separated** if, for s of order unity, we have that for any operator O_A supported on A and O_B supported on B that $\| [U_s O_A U_s^\dagger, O_B] \|$ and $\| [U_s^\dagger O_A U_s, O_B] \|$ are both bounded by $|A| \|O_A\| \|O_B\|$ times a quantity superpolynomially small in $\text{dist}(A, B)$.

This Lieb-Robinson bound can be proven, as explained above, for a system with a spectral gap. If there is a mobility gap, it can be proven under the following assumption (with slight modification in the definition of the corrected quasi-adiabatic continuation operator). We will consider later parameter-dependent Hamiltonians such that $\partial_s H_s = \sum_Z \partial_s H_Z(s)$ is supported on the sets of sites within distance R of two vertical lines (the solid and dashed vertical lines in Figs. 2 and 3). The derivatives $\partial_s H_Z(s)$ will be non-vanishing only for sets Z which are within distance R of one of these lines. We will be interested in sets A and B which are connected by part of one of these lines.

Consider a given set Z . The operator $\partial_s H_Z(s)$ for that set has matrix elements between the ground state and various excited states. We can define a density of states, $\rho_Z(E)$ by

$$\rho_Z(E) = \left| (1 - P_E) \left(\partial_s H_Z(s) \right) |\Psi_0\rangle \right|^2, \quad (107)$$

where P_E projects onto states with energy $E_0 + E$ or more and the partial derivatives are taken at $s = 0$ (later when we use this density of states, we will always be considering Hamiltonians which are unitarily equivalent for different s , so the density of states $\rho_Z(E)$ will be independent of s).

While it is expected that a disordered system will have states with energy of order $1/V$, we expect that only for Z close to certain points will $\partial_s H_Z(s)$ have non-negligible matrix elements to these states. In contrast, most Z are expected to have the property that $\partial_s H_Z(s)$ will only produce non-negligible matrix elements from the ground state to excited states with energies of order unity. In fact, we will require even weaker conditions than that. We will allow a typical Z to have non-negligible matrix elements to energy which are of order $1/L^\alpha$, for $\alpha < 1$.

Suppose there is an energy $\Delta \sim \gamma/L^\alpha$ such that the following property holds. We define $\mathcal{SLOW}$ to be the set of Z for which $\rho(\Delta)$ is bounded by ρ_{max} times $\|\partial_s H_Z(s)\|$, where ρ_{max} is a quantity which is superpolynomially small in L . We define $\mathcal{FAST}$ to be the remaining Z . Then, we define the corrected quasi-adiabatic continuation operator as

$$\mathcal{D}_s = \sum_Z \mathcal{D}_s^Z \quad (108)$$

as in Eq. (21). However, for $Z \in \mathcal{SLOW}$, we define $\mathcal{D}_s^Z$ with the cutoff $\lambda^< = \Delta$, while for $Z \in \mathcal{FAST}$ we use the cutoff $\lambda^< = \lambda_{min}$.

Then, this operator $\mathcal{D}_s$ continues to approximate the exact evolution up to superpolynomially small error bounded by $(\rho_{max}/\lambda^<) \sum_{Z \in \mathcal{SLOW}} \|\partial_s H_Z(s)\|$, with the additional error due to corrections from states below energy Δ .

Now, this operator $\mathcal{D}_s$ will separate sets A and B under mild assumptions on the density of states $\rho_Z(E)$. The operators $\mathcal{D}_s^Z$ for $Z \in \mathcal{FAST}$ will have large norm, but will decay exponentially in space. Assume $\lambda_{min} \geq \text{poly}(1/L)$. If we can find a segment of the line of length separating sets A, B as shown in Fig. 1. which scales as L^β/γ , for some β , with $\alpha < \beta \leq 1$, such that all Z in that segment are in $\mathcal{SLOW}$, then we will have the desired Lieb-Robinson bound: the $Z \in \mathcal{SLOW}$ will give operators $\mathcal{D}_s^Z$ bounded in norm by $\mathcal{O}((L^\alpha/\gamma) \|\partial_s H_Z(s)\|)$, and so have a Lieb-Robinson velocity. the $Z \in \mathcal{FAST}$ will have some effect on the dynamics in this segment, due to long-distance tails of $\partial_s H_Z(s)$ (i.e., even is $Z \in \mathcal{FAST}$, the operator $\partial_s H_Z(s)$ has support in $\mathcal{SLOW}$); however, this produces only corrections of order $\text{poly}(L)$ times a quantity decaying exponentially in L^α . Hence, we will have the desired separation.

HALL CONDUCTANCE ON A TORUS

We now prove Hall conductance on a torus. For a site i , we define it to have x and y coordinates $x(i)$ and $y(i)$. We consider a Hamiltonian with a mobility gap, with t_{max} superpolynomially large in L . We now define We define a parameter-dependent Hamiltonian $H(\theta_1, \theta_2, \phi_1, \phi_2)$ as follows. We pick two vertical lines at x_1, x_2 and two horizontal lines y_1, y_2 to insert flux. Let Q_X be defined by

$$Q_X = \sum_{i, x_1 \leq x(i) \leq x_2} q_i, \quad (109)$$

where $x(i)$ is the $\hat{x}$ -coordinate of site i and

$$Q_Y = \sum_{i, y_1 \leq y(i) \leq y_2} q_i. \quad (110)$$

FIG. 1: Line illustrating an example of separation on the torus. Sets A and B are marked by circles; there are periodic boundary conditions so B is a contiguous set. The flux is inserted along the dashed line connecting them. The short solid intervals mark sets $SLOW$ separating A and B as described.

We fix $|x_1 - x_2| = |y_1 - y_2| = L/2$.

Definition 8. Let H be any operator which can be written as $H = \sum_Z H_Z$ with the H_Z supported on a set Z of diameter less than $L/2$. Assume that all the sets Z are squares. Then, each such H_Z intersects at most one of the lines $x = x_1$ or $x = x_2$ and at most one of the lines $y = y_1$ or $y = y_2$. Then, define the **twisted operator**

$$H(\theta_1, \theta_2, \phi_1, \phi_2) = \sum_Z H_Z(\theta_1, \theta_2, \phi_1, \phi_2), \quad (111)$$

where $H_Z(\theta_1, \theta_2, \phi_1, \phi_2)$ is defined as follows. If the set Z intersects the vertical line $x = x_1$, then $H_Z(\theta_1, \theta_2, \phi_1, \phi_2) = \exp(i\theta_1 Q_X) H_Z(0, 0, \phi_1, \phi_2) \exp(-i\theta_1 Q_X)$; if the set Z intersects the vertical line $x = x_2$, then $H_Z(\theta_1, \theta_2, \phi_1, \phi_2) = \exp(-i\theta_2 Q_X) H_Z(0, 0, \phi_1, \phi_2) \exp(i\theta_2 Q_X)$; otherwise $H_Z(\theta_1, \theta_2, \phi_1, \phi_2) = H_Z(0, 0, \phi_1, \phi_2)$. If the set Z intersects the horizontal line $y = y_1$, then $H_Z(0, 0, \phi_1, \phi_2) = \exp(i\phi_1 Q_Y) H_Z \exp(-i\phi_1 Q_Y)$; if the set Z intersects the horizontal line $y = y_2$, then $H_Z(0, 0, \phi_1, \phi_2) = \exp(-i\phi_2 Q_Y) H_Z \exp(i\phi_2 Q_Y)$; otherwise $H_Z(0, 0, \phi_1, \phi_2) = H_Z$.

Note that we chose the sets Z to be squares so that they would be contiguous sets; thus, if Z was close to a line $x = x_1$ and contained some points with $x < x_1$ and some with $x > x_1$ then Z will intersect the line $x = x_1$, and similarly for the other three lines. This definition defines our parameter-dependent Hamiltonian, but we will also use it later for other operators.

In this section, we prove the following:

Theorem 2. Consider a Hamiltonian with a mobility gap, with t_{max} superpolynomially large in L , and λ_{min} greater than or equal to $1/\text{poly}(L)$. Suppose we can find lines x_1, x_2, y_1, y_2 with $|x_1 - x_2| = L/2$ and $|y_1 - y_2| = L/2$ such that the following holds. Consider any pair of lines. Let A be the set of points within distance $L/8$ of the intersection of that pair of lines. Consider any other pair of lines. Let B be the set of points within distance $L/8$ of the intersection of that pair of lines. Consider quasi-adiabatic evolution under any of the four different quasi-adiabatic evolution operators $\mathcal{D}^{\theta,1}, \mathcal{D}^{\theta,2}, \mathcal{D}^{\phi,1}, \mathcal{D}^{\phi,2}$ defined below. Suppose that A and B are separated under quasi-adiabatic evolution under all four such operators, Then, the Hall conductance is quantized to $n(e^2/h)$, for some integer n , up to an error which is superpolynomially small in L .

Note that by assumption the Hamiltonian has an (R, τ) unique ground state, with τ greater than or equal to $1/\text{poly}(L)$. We only sketch the proof, since it essentially follows [8] (this proof has some similarity with the Chern number approach[20] but avoids any averaging assumptions). We pick a parameter r which is superpolynomially small in L (the choice of r will be given later), with $2\pi/r = N$ for some integer N . Following [8], we define a set of set of N^2 different closed paths in parameter space. Each path keeps $\theta_2 = \phi_2 = 0$ throughout. Each path is defined by a given pair of numbers (θ_x, θ_y) with $\theta_x = mr$ and $\theta_y = nr$ for a pair of integers m, n in the range $0, \dots, N-1$. The paths start at $\theta_1 = \phi_1 = 0$. Then, we move to $\theta_1 = 0, \phi_1 = \theta_y$. Then we move to $\theta_1 = \theta_x, \phi_1 = \theta_y$. Then we move around a small square loop of size r at θ_x, θ_y as follows: we move to $\theta_1 = \theta_x + r, \phi_1 = \theta_y$, to $\theta_1 = \theta_x + r, \phi_1 = \theta_y + r$,

FIG. 2: Lines illustrating how the twists are defined on the torus. The twists θ_1, ϕ_1 affect interactions close to the vertical and horizontal solid lines, respectively, while the twists θ_2, ϕ_2 affect interactions close to the vertical and horizontal dashed lines.

$\theta_1 = \theta_x, \phi_1 = \theta_y + r$, and back to $\theta_1 = \theta_x, \phi_1 = \theta_y$. Finally, we return to the origin by moving to $\theta_1 = 0, \phi_1 = \theta_y$ and then to $\theta_0 = \phi_1 = 0$.

Thus, each path consists of 8 different line segments. We break it into three distinct parts. First, $V(m, n)$ moving from $0, 0$ to $\theta_1 = 0, \phi_1 = \theta_y$ and then to $\theta_1 = \theta_x, \phi_1 = \theta_y$. Then, $V_\square(m, n)$ moving around the small square loop. Finally, $V^\dagger(m, n)$ returning to the origin. We decompose the first part, $V(m, n) = U_2(m, n)U_1(m, n)$, with $U_1(m, n), U_2(m, n)$ corresponding to the two segments of that part. We also define unitaries $\tilde{U}_1(m, n), \tilde{U}_2(m, n)$ corresponding to evolution along the same path of θ_1, ϕ_1 but with $\theta_2 = -\theta_1$ and $\phi_2 = -\phi_1$. We also decompose the motion around the square loop as $V_\square(m, n) = U_D(m, n)U_L(m, n)U_U(m, n)U_R(m, n)$ corresponding to moving around the four different sides of the square (we use subscripts D, L, U, R indicating the the motion is first to the right, then up, then to the left, then down). We also define $\tilde{U}_D(m, n), \tilde{U}_L(m, n), \tilde{U}_U(m, n), \tilde{U}_R(m, n)$ corresponding to evolution around the same square but with $\theta_2 = -\theta_1$ and $\phi_2 = -\phi_1$.

Given these paths, we have to pick a quasi-adiabatic evolution operator to generate the various unitaries U and $\tilde{U}$. We define $\mathcal{D}^\theta(\theta, \phi)$ to be the quasi-adiabatic continuation operator which produces an infinitesimal change in θ starting at $\theta_1 = -\theta_2 = \theta$ and $\phi_1 = -\phi_2 = \phi$. That is, for $H_s = H(\theta + s, -\theta - s, \phi, -\phi)$, we define $\mathcal{D}^\theta(\theta, \phi) = \mathcal{D}_s$ at $s=0$. We define $\mathcal{D}^\phi(\theta, \phi)$ to produce an infinitesimal change in ϕ , again starting at $\theta_1 = -\theta_2 = \theta$ and $\phi_1 = -\phi_2 = \phi$. We use these operators $\mathcal{D}^\theta(\theta, \phi), \mathcal{D}^\phi(\theta, \phi)$ to generate the unitaries $\tilde{U}_1(m, n), \tilde{U}_2(m, n), \tilde{U}_{D,L,U,R}(m, n)$.

Let us consider the operator $\mathcal{D}^\theta(0, 0)$. For $\theta_1 = -\theta_2 = s$ and $\phi_1 = -\phi_2 = 0$, we have that $\partial_s H(s) = \sum_Z \partial_s H_Z(s)$, and $\partial_s H_Z(s)$ is nonvanishing if Z is within distance R of the line at $x = x_1$ or if Z is within distance R of the line at $x = x_2$. Let $O^{(1)}(s)$ denote the sum of terms in $\partial_s H(s)$ near the line at $x = x_1$ and let $O^{(2)}(s)$ denote the sum of terms in $\partial_s H(s)$ near the line at $x = x_2$, so that $\mathcal{D}_s = \mathcal{D}(H_s, O^{(1)}(s)) + \mathcal{D}(H_s, O^{(2)}(s))$. Under the assumption of a mobility gap, because of the superpolynomial localizability property, up to superpolynomially small error. we can approximate the operators $\mathcal{D}(H_s, O^{(1)})$ and $\mathcal{D}(H_s, O^{(2)})$ by operators $\mathcal{D}^{\theta,(1)}$ and $\mathcal{D}^{\theta,(2)}$ supported within distance less than $L/8$ of the respective lines $x = 0$ and $x = L/2$ and which are a sum of squares of operators on squares of size at most $L/2$. Then, we can apply the definition (8) to define

$$\mathcal{D}^{\theta,1}(\theta, \phi) = \mathcal{D}^{\theta,(1)}(\theta, 0, \phi, 0), \quad (112)$$

and

$$\mathcal{D}^{\theta,2}(\theta, \phi) = \mathcal{D}^{\theta,(2)}(0, -\theta, \phi, 0). \quad (113)$$

Note that

$$\mathcal{D}^\theta(\theta, 0) - \left(\mathcal{D}^{\theta,1}(\theta, 0) + \mathcal{D}^{\theta,2}(\theta, 0) \right) \quad (114)$$

is superpolynomially small. We define $\mathcal{D}^{\phi,(1)}$ and $\mathcal{D}^{\phi,(2)}$ in an analogous way by decomposing the operator $\mathcal{D}^\phi(0, 0)$, and then we have that

$$\mathcal{D}^\phi(0, \phi) - \left(\mathcal{D}^{\phi,1}(0, \phi) + \mathcal{D}^{\phi,2}(0, \phi) \right) \quad (115)$$

is superpolynomially small. We will use these operators $\mathcal{D}^{\theta,1}(\theta, \phi)$ and $\mathcal{D}^{\phi,1}(\theta, \phi)$ to generate the unitaries $U_1(m, n), U_2(m, n), U_{D,L,U,R}(m, n)$.

The reader will notice one fact about this choice of quasi-adiabatic evolution operators: they are all defined in terms of operators at $\theta = \phi = 0$ by applying a twist. This implies that the separation assumption can be defined solely in terms of the operators $\mathcal{D}$ at $\theta, \phi = 0$. For example,

$$\mathcal{S}' \exp\{i \int_0^s ds' \mathcal{D}^{\theta,1}(s', 0)\} = \exp(iQ_X s') \mathcal{S}' \exp\{i \int_0^s ds' (-Q_X + \mathcal{D}^{\theta,1}(0, 0))\} \exp(-iQ_X s'). \quad (116)$$

The proof rests on the following four facts. We sketch each in turn. First, for r sufficiently small, the evolution around the path $U(0, 0)$ returns the ground state to the ground state up to superpolynomial small error and up to some phase which is that is, up to superpolynomially small error, equal to $r^2/2\pi$ times the Hall conductance in units of e^2/h , plus corrections of order r^3 . That is, we claim that

Lemma 11. *The quantity*

$$|\langle \Psi_0, U(0, 0) \Psi_0 \rangle| \quad (117)$$

is superpolynomially close to unity for any r of order unity. Also, the quantity

$$|\langle \Psi_0, U(0, 0) \Psi_0 \rangle - \exp(ir^2 \frac{\sigma_{xy}}{2\pi} \frac{h}{e^2})| \quad (118)$$

is bounded by terms of order $\text{poly}(L)\mathcal{O}(r^3)$ plus terms which are superpolynomially close to unity.

Proof. Eq. (118) follows from a power series expansion of the quasi-adiabatic continuation operator. The terms of order r^2 in the expectation value in Eq. (118) arise from approximating, along each leg of the square, the evolution

$$U_s = \mathcal{S}' \exp\{i \int_0^s \mathcal{D}_s ds'\} = 1 + is\mathcal{D}_0 + \mathcal{O}(s^2). \quad (119)$$

The quasi-adiabatic evolution operator $i\mathcal{D}_0$ acting on the ground state is superpolynomially close to the derivative of the ground state with respect to the parameter s . Thus, to order r^2 , the expectation value $\langle \Psi_0, U(0, 0) \Psi_0 \rangle$ is superpolynomially close to $1 + r^2 2\text{Im}(\langle \partial_\phi \Psi(\theta, \phi), \partial_\theta \Psi(\theta, \phi) \rangle)$, where $\Psi(\theta, \phi)$ is the ground state of $H(\theta, 0, \phi, 0)$, and partial derivatives are taken at $\theta = \phi = 0$. However, this quantity $2\text{Im}(\langle \partial_\phi \Psi(\theta, \phi), \partial_\theta \Psi(\theta, \phi) \rangle)$ is related to the Hall conductance by the Kubo formula, so Eq. (118) follows to order r^2 . Using a bound on the norm of $\mathcal{D}$, we bound the terms of order r^3 by $\text{poly}(L)$.

To show Eq. (117), we show that the state $U(0, 0)\Psi_0$ has an energy which is superpolynomially close to E_0 . Then, using the assumed $\lambda_{\min}$, Eq. (117) will follow. We will estimate the energy by estimating the expectation value of H_Z for each Z in the state $U(0, 0)\Psi_0$.

Suppose first that Z is far from the point $x = x_1, y = y_1$ where two lines intersect (we use the word “far” to indicate something is a distance of order CL from something, and near otherwise). Note that $U(0, 0) = V_\odot(0, 0)$. We have $V_\odot(0, 0) = U_D(0, 0)U_L(0, 0)U_U(0, 0)U_R(0, 0)$. For simplicity, in this lemma we write $U_L = U_L(0, 0), U_R = U_R(0, 0)$, and so on. We claim that the operator $V_\odot(0, 0)$ can be approximated to superpolynomial accuracy by an operator supported near $x = x_1, y = y_1$ using the separation assumption and superpolynomial localizability property. So, if Z is far, from $x = x_1, y = y_1$, then $\| [H_Z, U(0, 0)] \|$ is superpolynomially small, so $\langle \Psi_0, U(0, 0)^\dagger H_Z U(0, 0) \Psi_0 \rangle$ is superpolynomially close to $\langle \Psi_0, H_Z \Psi_0 \rangle$.

We now show that $V_\odot(0, 0)$ can indeed be approximated by an operator supported near $x = x_1, y = y_1$. We will make repeated use of the basic identity for any two Hermitian operators a_s, b_s that, defining

$$u_{s_1, s_2} = \mathcal{S}' \exp\{i \int_{s_1}^{s_2} ds' b_{s'}\} \quad (120)$$

we have

$$\begin{aligned} \mathcal{S}' \exp\{i \int_0^s ds' a_{s'}\} &= \mathcal{S}' \exp\{i \int_0^s ds' u_{s', s} (a_{s'} - b_{s'}) u_{s', s}^\dagger\} u_{0, s} \\ &= u_{0, s} \mathcal{S}' \exp\{i \int_0^s ds' u_{s', 0}^\dagger (a_{s'} - b_{s'}) u_{s', 0}\}. \end{aligned} \quad (121)$$

Decomposing $V_\zeta(0, 0)$, we have

$$U_D U_L U_U U_R = U_D U_U \mathcal{S}' \exp\{-i U_U^\dagger \int_0^r ds' \mathcal{D}^{\theta,1}(r-s', r) U_U\} U_R \quad (122)$$

So, it suffices to show that $U_D U_U$ can be approximated by an operator supported near $x = x_1, y = y_1$ and similarly for $\mathcal{S}' \exp\{-i U_U^\dagger \int_0^r ds' \mathcal{D}^{\theta,1}(r-s, r) U_U\} U_R$. We have

$$U_D U_U = \mathcal{S}' \exp\{-i \int_0^r ds' \mathcal{D}^{\phi,1}(0, r-s')\} \mathcal{S}' \exp\{i \int_0^r ds' \mathcal{D}^{\phi,1}(r, s')\}. \quad (123)$$

Define $A(s') = \mathcal{D}^{\phi,1}(0, s') - \mathcal{D}^{\phi,1}(r, s')$. Define $W_{s_1, s_2} = \mathcal{S}' \exp\{i \int_{s_1}^{s_2} ds' \mathcal{D}^{\phi,1}(r, s')\}$, so that $U_U = W_{0, r}$. Then,

$$U_D U_U = \mathcal{S}' \exp\{-i \int_0^r ds' W_{s', r} A(r-s') W_{s', r}^\dagger\}. \quad (124)$$

Note that $A(s')$ can be approximated by an operator supported near $x = x_1, y = y_1$ using the superpolynomially localizability property, and so using the separation assumption, $W_{s', r} A(r-s') W_{s', r}^\dagger$ can also be approximated by such an operator to superpolynomial accuracy. Thus, $U_D U_U$ can be approximated by such an operator. We next consider $\mathcal{S}' \exp\{-i U_U^\dagger \int_0^r ds' \mathcal{D}^{\theta,1}(r-s', r) U_U\} U_R$. Define

$$B(s) = U_U^\dagger \mathcal{D}^{\theta,1}(r-s, r) U_U - \mathcal{D}^{\theta,1}(r-s, r), \quad (125)$$

and define $Y_{s_1, s_2} = \mathcal{S}' \exp\{-i \int_{s_1}^{s_2} ds' \mathcal{D}^{\theta,1}(s-s', r)\}$ so that $U_L = Y_{0, r}$. Then,

$$\mathcal{S}' \exp\{-i U_U^\dagger \int_0^r ds' \mathcal{D}^{\theta,1}(r-s, r) U_U\} U_R = \mathcal{S}' \exp\{-i \int_0^r ds' Y_{s', r} B(s') Y_{s', r}^\dagger\} U_L U_R. \quad (126)$$

Note that $B(s')$ can be approximated by an operator supported near $x = x_1, y = y_1$ using the superpolynomially localizability property, and so using the separation assumption, $Y_{s', r} B(s') Y_{s', r}^\dagger$ can also be approximated by such an operator to superpolynomial accuracy. Thus, $\mathcal{S}' \exp\{-i \int_0^r ds' Y_{s', r} B(s') Y_{s', r}^\dagger\}$ can also be approximated by such an operator. Finally, one may show that $U_L U_R$ can be approximated by such an operator in a similar way as to the proof that $U_D U_U$ could be approximated by such an operator.

Now, suppose that Z is close to both $y = y_1$ and $x = x_1$. Consider the expectation value $\langle \Psi_0, U_R^\dagger U_U^\dagger U_L^\dagger U_D^\dagger H_Z U_D U_L U_U U_R \Psi_0 \rangle$. Note that $\tilde{U}_D^\dagger H_Z \tilde{U}_D$ is superpolynomially close to $U_D^\dagger H_Z U_D$. So, we may consider $\langle \Psi_0, U_R^\dagger U_U^\dagger U_L^\dagger \tilde{U}_D^\dagger H_Z \tilde{U}_D U_L U_U U_R \Psi_0 \rangle$. Using the separation assumption, $\tilde{U}_D^\dagger H_Z \tilde{U}_D$ has small commutator with $\mathcal{D}^{\theta,2}$. So, $U_L^\dagger \tilde{U}_D^\dagger H_Z \tilde{U}_D U_L$ is superpolynomially close to $\tilde{U}_L^\dagger \tilde{U}_D^\dagger H_Z \tilde{U}_D \tilde{U}_L$ (this calculation uses the identity (121) and similar decomposition of unitaries into ordered exponentials as the above case, so we omit the details). Repeating this, we find that $\langle \Psi_0, U_R^\dagger U_U^\dagger U_L^\dagger U_D^\dagger H_Z U_D U_L U_U U_R \Psi_0 \rangle$ is superpolynomially close to $\langle \Psi_0, \tilde{U}_R^\dagger \tilde{U}_U^\dagger \tilde{U}_L^\dagger \tilde{U}_D^\dagger H_Z \tilde{U}_D \tilde{U}_L \tilde{U}_U \tilde{U}_R \Psi_0 \rangle$. However, $\tilde{U}_D \tilde{U}_L \tilde{U}_U \tilde{U}_R \Psi_0$ is superpolynomially close to Ψ_0 times a phase. Therefore, $\langle \Psi_0, U_R^\dagger U_U^\dagger U_L^\dagger U_D^\dagger H_Z U_D U_L U_U U_R \Psi_0 \rangle$ is superpolynomially close to $\langle \Psi_0, H_Z \Psi_0 \rangle$. This completes the possible cases. $\square$

Let us discuss one point in the above proof. This approach used to show Eq. (117) is different than the approach used in [8], where it was simply noted that quasi-adiabatic evolution around a closed loop in a gapped region of parameter space approximates adiabatic evolution and hence returns the ground state to the ground state up to small error; we use this different approach because here we do not want to rely on any assumption of a mobility gap for parameter values other than $\theta = \phi = 0$. In [8], since r was taken superpolynomially small, evolution within the region of parameter space with $|\theta_x|, |\theta_y| \leq r$ preserved the spectral gap assumed in that paper. In this paper, we could try to follow that idea and show that a mobility gap at $\theta = \phi = 0$ implies a mobility gap for superpolynomially small change in the Hamiltonian; this may be possible, but since an alternate method is available we preferred not to do this.

The second property is that the evolution around all loops returns the ground state to the ground state and produces the same expectation value up to superpolynomially small error. That is,

Lemma 12. *Define*

$$z(m, n) = \langle \Psi_0, U(m, n) \Psi_0 \rangle. \quad (127)$$

Then,

$$|z_{m,n} - z_{0,0}| \quad (128)$$

is superpolynomially small.

Proof. To prove this, note that the expectation value is equal to $\langle \Psi_0 | V(m,n)^\dagger V_\zeta(m,n) V(m,n) | \Psi_0 \rangle$. The operator V_ζ can be approximated to superpolynomial accuracy by an operator supported near $x = x_1, y = y_1$. So, $U_2(m,n)^\dagger V_\zeta(m,n) U_2(m,n)$ is superpolynomially close to $\tilde{U}_2(m,n)^\dagger V_\zeta(m,n) \tilde{U}_2(m,n)$. Again using the Lieb-Robinson bounds, $U_1(m,n)^\dagger U_2(m,n)^\dagger V_\zeta(m,n) U_2(m,n) U_1(m,n)$ is superpolynomially close to $\tilde{U}_1(m,n)^\dagger \tilde{U}_2(m,n)^\dagger V_\zeta(m,n) \tilde{U}_2(m,n) \tilde{U}_1(m,n)$. However, $\tilde{U}_2(m,n) \tilde{U}_1(m,n) | \Psi_0 \rangle = \exp(iQ_X \theta_1) \exp(iQ_Y \theta_2) | \Psi_0 \rangle$ and $V_\zeta(m,n)$ is superpolynomially close to $\exp(iQ_X \theta_1) \exp(iQ_Y \theta_2) V_\zeta(m,n) \exp(-iQ_X \theta_1) \exp(-iQ_Y \theta_2)$. So, $\langle \Psi_0 | U(m,n) | \Psi_0 \rangle$ is superpolynomially close to $\langle \Psi_0 | U(0,0) | \Psi_0 \rangle$. $\square$

The third property is that the product $\left(U(N-1, N-1) U(N-2, N-1) \dots U(0, N-1) \right) \left(U(N-1, N-2) \dots U(0, N-2) \right) \dots \left(U(N-1, 0) \dots U(0, 0) \right)$ is exactly equal to the unitary operator U_{big} corresponding to quasi-adiabatic evolution around a big loop of size 2π : moving from $\theta_1 = \phi_1 = 0$ to $\theta_1 = 2\pi, \phi_1 = 0$, to $\theta_1 = \phi_1 = 2\pi$ to $\theta_1 = 0, \phi_1 = 2\pi$, to $\theta_1 = \phi_1 = 0$. This is the evolution decomposition in [8].

The fourth property is that the phase due to evolution around the big loop is equal to unity up to superpolynomially small error. To prove this, we need to show that evolution along any of the four sides of the big loop (for example, from $\theta_1 = \phi_1 = 0$ to $\theta_1 = 2\pi, \phi_1 = 0$) send the ground state to the ground state up to a phase, up to superpolynomially small error. Then, the phase will cancel between opposite sides of the loop. However, the fact that evolution along a single side sends the ground state to the ground state up to a phase and up to superpolynomially small error follows from the same argument as in the Lieb-Schultz-Mattis proof previously. Thus,

$$\langle \Psi_0, U_{big} \Psi_0 \rangle \quad (129)$$

is superpolynomially close to unity.

We then approximate the phase of evolution around the large loop by the product of phases for evolution around each small loop, following the Appendix in [8]. That is, we approximate:

$$1 \approx \langle \Psi_0, U_{big} \Psi_0 \rangle \approx \prod_{m,n} z_{m,n}. \quad (130)$$

The error in the second approximation is due to the fact that each small loop has some “leakage” outside the ground state. That is, $U(m,n) \Psi_0$ has some component perpendicular to the ground state. Define $E_{m,n}$ to be the $|(1 - P_0)U(m,n)\Psi_0|^2 = 1 - |z_{m,n}|^2$. Then, the difference

$$|\langle \Psi_0, U_{big} \Psi_0 \rangle - \prod_{m,n} z_{m,n}| \leq \sum_{m,n} \sqrt{E_{m,n}}. \quad (131)$$

However, by lemma (11), the quantity $E_{0,0}$ is superpolynomially small and so by lemma (12), the quantity $E_{m,n}$ is superpolynomially small for all m,n . The number of small loops scales as $1/r^2$. Hence, we can pick an r which is superpolynomially large such that the difference in Eq. (131) is negligible. Thus, $|1 - \prod_{m,n} z_{m,n}|$ is superpolynomially small. Then, since the phase is almost the same for every small loops, the phase around the loop with $m = n = 0$ is close to $2\pi n/N = 2\pi(r/2\pi)^2$ for some integer n . Hence the Hall conductance is close to ne^2/h .

Note that we used three properties of these operators $\mathcal{D}^\theta(\theta, \phi)$ and $\mathcal{D}^\phi(\theta, \phi)$. First, that each operator can be approximated, to superpolynomial accuracy, by a sum of operator operators supported close to the respective lines $x = x_1, x_2$ or $y = y_1, y_2$, each of which is approximated by a sum of operators on squares of increasing size but superpolynomially decaying strength. Second, the separation assumption. Third, evolution of the ground state under $\mathcal{D}^\theta$ or $\mathcal{D}^\phi$ approximates, to superpolynomial accuracy, the adiabatic evolution of the ground state, and hence gives a state which is superpolynomially close to $\exp(iQ_X \theta) \exp(iQ_Y \phi) \Psi_0$. Thus, any operators which satisfy these three properties would suffice.

HALL CONDUCTANCE ON AN ANNULUS

We now consider open boundary conditions. Specifically, we consider a system on an annulus. In this case, a system will not have a gap: there will be gapless edge modes. However, there is still a bulk gap. We need to define this. We let $\mathcal{I}$ and $\mathcal{O}$ denote the sites on the inner and outer edges of the annulus. We let $\mathcal{B}$ denote the sites s such that $\text{dist}(s, \mathcal{I}) \geq L/3, \text{dist}(s, \mathcal{O}) \geq L/3$. That is, $\mathcal{B}$ is a ring around the inside of the annulus, which we call the “bulk”. The constant factor $1/3$ is not particularly important; we simply want a constant less than $1/2$ (so that the width of the ring scales linearly in L) and greater than 0 (so that the distance from the edges also scales linearly with L). We use x and y coordinates to label sites, and let the line $y = 0$ correspond to halfway between the inner and outer rings of the annulus, so that $\mathcal{B}$ includes points with $-L/6 \leq y \leq L/6$.

Definition 9. We say that a system has a **bulk mobility gap** γ and localization length ξ and localization constant c_{loc} up to time t_{max} if, for any operator O supported on set A , there exists an operator $W_{\gamma,G}^{loc}(O, t)$ with the following properties. First, for any l , $W_{\gamma,G}^{loc}(O, t)$ can be approximated by a sum of operators $P_I + P_O + P_{bulk}$, with P_I is supported on $b_l(\mathcal{I})$, P_O is supported on $b_l(\mathcal{O})$, and P_{bulk} is supported on $b_l(\mathcal{B})$, up to an error in operator norm bounded by

$$c_{loc} \exp(-l/\xi) \|W_{\gamma,G}(O)\| + \max_{|\omega| \geq \gamma} |\tilde{G}(\omega)| \|O\| \quad (132)$$

with

$$\|P_I\| \leq \|O\| c_{loc} \exp(-\text{dist}(A, \mathcal{I})/\xi), \quad (133)$$

$$\|P_O\| \leq \|O\| c_{loc} \exp(-\text{dist}(A, \mathcal{O})/\xi). \quad (134)$$

Second, we require that the state produced by acting with $W_{\gamma,G}(O)(t) = \exp(iH_0 t) W_{\gamma,G}(O) \exp(-iH_0 t)$ on the ground state is equal to the state produced by acting with an operator $W_{\gamma,G}^{loc}(O, t)$ on the ground state, i.e.,

$$W_{\gamma,q}(O)(t) \Psi_0 = W_{\gamma,G}^{loc}(O, t) \Psi_0. \quad (135)$$

Third, we have

$$\|W_{\gamma,G}^{loc}(O, t)\| \leq \|W_{\gamma,G}(O)\|. \quad (136)$$

Definition 10. We say that a Hamiltonian H has an (l, τ) **unique bulk ground state** if the following holds. Given any density matrix ρ such that, for all sets $A \subset b_l(\mathcal{B})$ with $\text{diam}(A) \leq l$ we have

$$\|\text{Tr}_{\bar{A}}(\rho - P_0)\|_1 \leq \epsilon, \quad (137)$$

then

$$\|\text{Tr}_{\bar{B}}(\rho - P_0)\|_1 \leq \tau \sqrt{\epsilon} \quad (138)$$

The definition of a unique bulk state is certainly necessary. Let us explain why. Consider a fractional Hall system defined on an annulus. The system has a bulk gap. However, the system does not have a unique bulk state according to our definition: physically, one expects q different bulk states in a $1/q$ Laughlin wavefunction. Such a system will also not have an integer Hall conductance. Thus, to prove integer quantization we need to make the assumption of a unique bulk state.

We now define twisted boundary conditions. We pick two vertical lines at x_1, x_2 with $|x_1 - x_2| = L/2$ and a single horizontal line at $y = 0$. Let Q_X be defined by

$$Q_X = \sum_{i, x_1 \leq x(i) \leq x_2} q_i, \quad (139)$$

where $x(i)$ is the $\hat{x}$ -coordinate of site i and

$$Q_Y = \sum_{i, y_i \geq 0} q_i. \quad (140)$$

FIG. 3: Lines illustrating how the twists are defined on the annulus. The twists θ_1, θ_2 affect interactions close to the vertical solid and dashed lines, respectively, while the twist ϕ affects interactions close to the horizontal dashed line. Regions $\mathcal{I}$ and $\mathcal{O}$ are the top and bottom rectangles filled with angled lines, respectively.

Definition 11. Let H be any operator which can be written as $H = \sum_Z H_Z$ with the H_Z supported on a set Z of diameter less than $L/2$. Assume that all the sets Z are squares. Then, each such H_Z intersects at most one of the lines $x = x_1$ or $x = x_2$ and at most one of the lines $y = y_1$ or $y = y_2$. Then, define the **twisted operator**

$$H(\theta_1, \theta_2, \phi) \quad (141)$$

as follows. Let

$$H(\theta_1, \theta_2, \phi) = \sum_Z H_Z(\theta_1, \theta_2, \phi), \quad (142)$$

where $H_Z(\theta_1, \theta_2, \phi)$ is defined as follows. If the set Z intersects the vertical line $x = x_1$, then $H_Z(\theta_1, \theta_2, \phi) = \exp(i\theta_1 Q_X) H_Z(0, 0, \phi) \exp(-i\theta_1 Q_X)$; if the set Z intersects the vertical line $x = x_2$, then $H_Z(\theta_1, \theta_2, \phi) = \exp(-i\theta_2 Q_X) H_Z(0, 0, \phi) \exp(i\theta_2 Q_X)$; otherwise $H_Z(\theta_1, \theta_2, \phi) = H_Z(0, 0, \phi)$. Finally, define $H_Z(0, 0, \phi) = \exp(i\phi Q_Y) H_Z \exp(-i\phi Q_Y)$.

Note that there is only one horizontal line for the annulus, while we had two for the torus.

In this section, we prove the following:

Theorem 3. Consider a Hamiltonian with a bulk mobility gap, with t_{max} superpolynomially large in L , and λ_{min} greater than or equal to $1/\text{poly}(L)$, and with a $(c_0 L, \tau)$ unique bulk state, with τ greater than or equal to $1/\text{poly}(L)$, for sufficiently small c_0 . Suppose we can find lines x_1, x_2 with $|x_1 - x_2| = L/2$ such that the following holds. Let A be the set of points within distance $L/6$ of the intersection of the line $x = x_2$ with $y = 0$. Let B be the union of the set of points within distance $L/6$ of the other line and the set of points within distance $L/6$ of either edge of the annulus. Consider quasi-adiabatic evolution under the quasi-adiabatic evolution operators defined below. Suppose that A and B are separated under quasi-adiabatic evolution under all such operators. Then, the Hall conductance is quantized to $n(e^2/h)$, for some integer n , up to an error which is superpolynomially small in L .

Note that we allow an operator on the line $x = x_1$ to evolve under quasi-adiabatic evolution to an operator which cannot be approximated by an operator supported near $x = x_1$. We allow the operator to spread out along the line, and along the boundary of the sample, having a large effect on sites along the boundary, but we require that it not penetrate into the bulk near the line $x = x_2$. This is needed for the second property below.

The proof essentially follows the above proof. We again define a set of set of N^2 different closed paths in parameter space. Each path keeps $\theta_2 = \phi = 0$ throughout. Each path is defined by a given pair of numbers (θ_x, θ_y) with $\theta_x = mr$ and $\theta_y = nr$ for a pair of integers m, n in the range $0, \dots, N-1$. The paths start at $\theta_1 = \phi = 0$. Then, we move to $\theta_1 = 0, \phi = \theta_y$. Then we move to $\theta_1 = \theta_x, \phi = \theta_y$. Then we move around a small square loop of size r at θ_x, θ_y as follows: we move to $\theta_1 = \theta_x + r, \phi = \theta_y$, to $\theta_1 = \theta_x + r, \phi = \theta_y + r$, to $\theta_1 = \theta_x, \phi = \theta_y + r$, and back to $\theta_1 = \theta_x, \phi = \theta_y$. Finally, we return to the origin by moving to $\theta_1 = 0, \phi = \theta_y$ and then to $\theta_0 = \phi = 0$.

Thus, each path consists of 8 different line segments. We break it into three distinct parts. First, $V(m, n)$ moving from $0, 0$ to $\theta_1 = 0, \phi = \theta_y$. Then we move to $\theta_1 = \theta_x, \phi = \theta_y$. Then, $V_\zeta(m, n)$ moving around the small square loop. Finally, $V^\dagger(m, n)$ returning to the origin. We write the first part, $V(m, n) = U_2(m, n)U_1(m, n)$, with $U_1(m, n), U_2(m, n)$ corresponding to the two segments of that part. We also define unitary $\tilde{U}_1(m, n)$ and $\tilde{U}_2(m, n)$ corresponding to evolution along the same path of θ_1, ϕ but with $\theta_2 = -\theta_1$.

Given these paths, we have to pick a quasi-adiabatic evolution operator to generate the various unitaries U and $\tilde{U}$. We define $\mathcal{D}^\theta(\theta, \phi)$ to be the quasi-adiabatic continuation operator which produces an infinitesimal change in θ starting at $\theta_1 = -\theta_2 = \theta$ and the given ϕ . That is, for $H_s = H(\theta + s, -\theta - s, \phi)$, we define $\mathcal{D}^\theta(\theta, \phi) = \mathcal{D}_s$ at $s=0$. We define $\mathcal{D}^\phi(\theta, \phi)$ to produce an infinitesimal change in ϕ , again starting at $\theta_1 = -\theta_2 = \theta$ and the given ϕ . We use these operators $\mathcal{D}^\theta(\theta, \phi), \mathcal{D}^\phi(\theta, \phi)$ to generate the unitaries $\tilde{U}_1(m, n), \tilde{U}_2(m, n), \tilde{U}_{D,L,U,R}(m, n)$. Let us consider the operator $\mathcal{D}^\theta(0, 0)$. For $\theta_1 = -\theta_2 = s$ and $\phi = 0$, we have that $\partial_s H(s) = \sum_Z \partial_s H_Z(s)$, and $\partial_s H_Z(s)$ is nonvanishing if Z is within distance R of the line at $x = x_1$ or if Z is within distance R of the line at $x = x_2$. Let $O^{(1)}(s)$ denote the sum of terms in $\partial_s H(s)$ near the line at $x = x_1$ and let $O^{(2)}(s)$ denote the sum of terms in $\partial_s H(s)$ near the line at $x = x_2$, so that $\mathcal{D}_s = \mathcal{D}(H_s, O^{(1)}(s)) + \mathcal{D}(H_s, O^{(2)}(s))$. Under the assumption of a mobility gap, because of the superpolynomial localizability property, up to superpolynomially small error, we can approximate the operators $\mathcal{D}(H_s, O^{(1)})$ and $\mathcal{D}(H_s, O^{(2)})$ by operators $\mathcal{D}_s^{(1)}$ and $\mathcal{D}_s^{(2)}$ supported within distance less than $L/8$ of the respective lines $x = 0$ and $x = L/2$ and which are a sum of squares of operators on squares of size at most $L/2$. Then, we can apply the definition (8) to define

$$\mathcal{D}^{\theta,1}(\theta, \phi) = \mathcal{D}_s^{(1)}(\theta, 0, \phi), \quad (143)$$

and

$$\mathcal{D}^{\theta,2}(\theta, \phi) = \mathcal{D}_s^{(2)}(0, -\theta, \phi). \quad (144)$$

Note that

$$\mathcal{D}^\theta(\theta, 0) - (\mathcal{D}^{\theta,1}(\theta, 0) + \mathcal{D}^{\theta,2}(\theta, 0)) \quad (145)$$

is superpolynomially small. Similarly, we define $\mathcal{D}^{\phi,1}$ as follows: we approximate $\mathcal{D}^\phi(0, 0)$ by an operator $\text{cal} \mathcal{D}_s$ which is a sum of operators supported on squares of size at most $L/2$. Then, we apply definition (8) to define

$$\mathcal{D}^{\phi,1}(\theta, \phi) = \mathcal{D}_s(\theta, 0, \phi). \quad (146)$$

Note that $\mathcal{D}^\phi(\theta, \phi)$ is superpolynomially close to $\mathcal{D}_s(\theta, -\theta, \phi)$, so at $\theta \neq 0$, the operators $\mathcal{D}^{\phi,1}(\theta, \phi)$ and $\mathcal{D}^\phi(\theta, \phi)$ are not necessarily superpolynomially close to each other. We will use these operators $\mathcal{D}^{\theta,1}(\theta, \phi)$ and $\mathcal{D}^{\phi,1}(\theta, \phi)$ to generate the unitaries $U_1(m, n), U_2(m, n), U_{D,L,U,R}(m, n)$.

The proof rests on the following four facts. We sketch each in turn.

First, for r sufficiently small, the evolution around the path $U(0, 0)$ returns the ground state to the ground state up to superpolynomial small error and up to some phase which is that is, up to superpolynomially small error, equal to $r^2/2\pi$ times the Hall conductance in units of e^2/h , plus corrections of order r^3 . That is, similar to lemma (11) above, we claim that

Lemma 13. *The quantity*

$$|\langle \Psi_0, U(0, 0) \Psi_0 \rangle| \quad (147)$$

is superpolynomially close to unity for any r . Also, the quantity

$$|\langle \Psi_0, U(0, 0) \Psi_0 \rangle - \exp(ir^2 \frac{\sigma_{xy}}{2\pi} \frac{h}{e^2})| \quad (148)$$

is bounded by terms of order $\text{poly}(L)\mathcal{O}(r^3)$ plus terms which are superpolynomially close to unity.

The proof of this is analogous to the torus case.

The second property is that the evolution around all loops returns the ground state to the ground state and produces the same phase up to superpolynomially small error. To prove this, note that the desired expectation value is $\langle \Psi_0 | V(m, n)^\dagger V_\zeta(m, n) V(m, n) | \Psi_0 \rangle$. The operator V_ζ can be approximated to superpolynomial accuracy by an operator supported near $x = x_1, y = y_1$, using the Lieb-Robinson bound for quasi-adiabatic continuation. So, $U_2(m, n)V_\zeta(m, n)U_2(m, n)$ is superpolynomially close to $\tilde{U}_2(m, n)^\dagger V_\zeta(m, n)\tilde{U}_2(m, n)$. However,

$\tilde{U}_2(m, n)^\dagger U_1(m, n)|\Psi_0\rangle = \exp(iQ_X\theta_1)\exp(iQ_Y\phi)|\Psi_0\rangle$ for $\theta_1 = mr, \phi = nr$, and $V_\odot(m, n)$ is superpolynomially close to $\exp(iQ_X\theta_1)\exp(iQ_Y\phi)V_\odot(m, n)\exp(-iQ_X\theta_1)\exp(-iQ_Y\phi)$. So, $\langle\Psi_0|U(m, n)|\Psi_0\rangle$ is superpolynomially close to $\langle\Psi_0|U(0, 0)|\Psi_0\rangle$. This argument is almost identical to the torus case, except different sets were required to be separated.

The third property is that the product $\left(U(N-1, N-1)U(N-2, N-1)\dots U(0, N-1)\right)\left(U(N-1, N-2)\dots U(0, N-2)\right)\dots\left(U(N-1, 0)\dots U(0, 0)\right)$ is exactly equal to the unitary operator corresponding to quasi-adiabatic evolution around a big loop of size 2π : moving from $\theta_1 = \phi_1 = 0$ to $\theta_1 = 2\pi, \phi_1 = 0$, to $\theta_1 = \phi_1 = 2\pi$ to $\theta_1 = 0, \phi_1 = 2\pi$, to $\theta_1 = \phi_1 = 0$. This is the evolution decomposition in [8].

The fourth property is that the phase due to evolution around the big loop is equal to unity up to superpolynomially small error. To show this, note that evolution along the sides of the loop where ϕ increases from 0 to 2π , or decreases from 2π to zero, is given by an operator that is, up to superpolynomially small error, supported in $\mathcal{B}$. Define this operator to be $U_{2\pi}^\phi$. Acting on the ground state, this operator $U_{2\pi}^\phi$ only produces a phase, since it approximates the exact evolution under a unitary transformation of the Hamiltonian. This phase is non-trivial, being $z_\phi \equiv \exp(-i2\pi\bar{Q}_Y)$, where $\bar{Q}_Y = \langle\Psi_0|Q_Y|\Psi_0\rangle$.

Let $U_{2\pi}^\theta$ define the evolution along the side of the big loop where θ increases from 0 to 2π . We are interested in the action of $U_{2\pi}^\phi$ on the state $U_{2\pi}^\theta|\Psi_0\rangle$. We claim that $U_{2\pi}^\phi U_{2\pi}^\theta|\Psi_0\rangle \approx z_\phi U_{2\pi}^\theta|\Psi_0\rangle$, and we will show this in the next paragraph. Given that this is true, then the desired fourth property follows:

$$\langle\Psi_0|\left(U_{2\pi}^\phi\right)^\dagger\left(U_{2\pi}^\theta\right)^\dagger U_{2\pi}^\phi U_{2\pi}^\theta|\Psi_0\rangle \approx \bar{z}_\phi z_\phi \langle\Psi_0|\left(U_{2\pi}^\theta\right)^\dagger U_{2\pi}^\theta|\Psi_0\rangle = 1. \quad (149)$$

To show the claim, it suffices to show that the reduced density matrix of $U_{2\pi}^\theta|\Psi_0\rangle$ on $\mathcal{B}$ is close to the reduced density matrix of $|\Psi_0\rangle$ on $\mathcal{B}$ since $U_{2\pi}^\theta$ is approximated by an operator supported on $\mathcal{B}$. To show this, we use the assumption of a unique bulk state: if we can show that the expectation value in the state $U_{2\pi}^\theta|\Psi_0\rangle$ of all operators O supported on $\mathcal{B}$ supported on sets of diameter at most c_0L is close to that in the ground, then we are done. If O is distance of order L from $x = x_1$, then this follows from the locality of the quasi-adiabatic continuation operator. If O is close to $x = x_1$, then for sufficiently small c_0 , the operator O is supported a distance of order L from $x = x_2$ by assumption. Define

$$\begin{aligned} R_{2\pi} &\equiv \mathcal{S}' \exp\left\{i \int_0^{2\pi} ds' \mathcal{D}_{s'}^{(1)} + \mathcal{D}_{s'}^{(2)}\right\} \\ &= U_{2\pi}^\theta \mathcal{S}' \exp\left\{i \int_0^{2\pi} ds' (U_{s'}^\theta)^\dagger \mathcal{D}^{(2)} U_{s'}^\theta\right\}, \end{aligned} \quad (150)$$

where $U_s^\theta = \mathcal{S}' \exp\left\{i \int_0^{2\pi} ds' \mathcal{D}_{s'}^{(1)}\right\}$. Using the assumption of separation, the operator $\mathcal{S}' \exp\left\{i \int_0^{2\pi} ds' (U_{s'}^\theta)^\dagger \mathcal{D}^{(2)} U_{s'}^\theta\right\}$ can be approximated to superpolynomial accuracy by an operator supported away from the intersection of $\mathcal{B}$ with $x = x_1$. So,

$$\langle\Psi_0|\left(U_{2\pi}^\theta\right)^\dagger O U_{2\pi}^\theta|\Psi_0\rangle \approx \langle\Psi_0|R_{2\pi}^\dagger O R_{2\pi}|\Psi_0\rangle. \quad (151)$$

However, $R_{2\pi}$ describes quasi-adiabatic continuation along a unitarily equivalent path of Hamiltonians, and $R_{2\pi}|\Psi_0\rangle = |\Psi_0\rangle$. So, this completes the proof that the expectation value of O is almost the same for all operators O of diameter at most c_0L supported in $\mathcal{B}$.

Given these four properties, we can complete in the same manner as in the torus case: we approximate the phase of evolution around the large loop by the product of phases for evolution around each small loop. The number of small loops scales as $1/r^2$, but we can find an r which is superpolynomially small but for which this leakage is negligible. Hence, the product of the phases is superpolynomially close to unity. Then, since the phase is almost the same for every small loops, the phase around the loop with $m = n = 0$ is close to $2\pi n/N = 2\pi(r/2\pi)^2$ for some integer n . Hence the Hall conductance is close to ne^2/h .

DISCUSSION

This paper mostly consisted of a series of definitions. Once the correct definitions are found, the corrected quasi-adiabatic continuation operator could be constructed straightforwardly. This allowed us to carry over many of the

previous results obtained with these operators in the case of a spectral gap in a straightforward way to the case of a mobility gap. It is likely that there are other applications of these ideas.

In the appendix, we presented quasi-adiabatic continuation operators that have very rapid decay in space, simplifying and tightening previous estimates.

Acknowledgments I thank C. Nayak and T. J. Osborne for useful discussions on disordered systems. I thank S. Bravyi and S. Michalakis for useful discussions on filter functions.

Optimized Quasi-Adiabatic Continuation

In this section, we construct an infinitely differentiable function $\tilde{F}(\omega)$ such that $\tilde{F}(\omega) = -1/\omega$ for $|\omega| \geq 1$ and such that the Fourier transform $F(t)$ decays exponentially in a polynomial of t . Our general strategy to construct this function is to construct an infinitely differentiable function equal to 1 for $|\omega| \geq 1$ and vanishing at $\omega = 0$, and then multiply this function by $1/\omega$.

Then, in the next section we show the application of this function to construct an exact (in that it can be used to exactly describe evolution of the ground state of a gapped Hamiltonian under a parameter change) quasi-adiabatic operator with good decay properties in space (we present this in detail only for a system with a spectral gap), and show Lieb-Robinson bounds for this operator and discuss the best possible bounds. Then, we present some discussion of the problem of optimizing over functions. Finally, we present applications in the last section.

Let $\tilde{f}(\omega)$ be even and have the property that $\tilde{f}(\omega) = 0$ for $\omega = 0$ and $\tilde{f}(\omega) = 1$ for $|\omega| \geq 1$. Let $f(t)$ be the Fourier transform of $\tilde{f}(\omega)$. Then, define $F(t)$ by

$$F(t) = \frac{i}{2} \int du f(u) \text{sign}(t - u), \quad (152)$$

where $\text{sign}(t - u)$ is the sign function: $\text{sign}(t - u) = 1$ for $t > u$, $\text{sign}(t - u) = -1$ for $t < u$, and $\text{sign}(0) = 0$. We now show the time decay of $F(t)$ and we show that the Fourier transform $\tilde{F}(\omega)$ is equal to $-1/\omega$ for $|\omega| \geq 1$, as desired.

Lemma 14. *Let $F(t)$ be as defined in 152. Let $\tilde{F}(\omega)$ be the Fourier transform of $F(t)$. Then,*

$$|F(t)| \leq \left| \int_{|t|}^{\infty} f(u) du \right|, \quad (153)$$

and

$$\tilde{F}(\omega) = \frac{-1}{\omega} \tilde{f}(\omega). \quad (154)$$

Proof. Assume, without loss of generality, that $t \geq 0$. Then, we have $|F(t)| \leq \left| \int_t^{\infty} f(u) du \right|/2 + \left| \int_{-\infty}^t f(u) du \right|/2$. Since $\tilde{f}(0) = 0$, we have $\left| \int_{-\infty}^t f(u) du \right| = \left| \int_t^{\infty} f(u) du \right|$. Thus, $|F(t)| \leq \left| \int_t^{\infty} f(u) du \right|$.

We have

$$\tilde{F}(\omega) = \frac{i}{2} \int dt \exp(i\omega t) \int du f(u) \text{sign}(t - u). \quad (155)$$

Integrating by parts in t , we have

$$\begin{aligned} \tilde{F}(\omega) &= \frac{-1}{\omega} \int dt \exp(i\omega t) \int du f(u) \delta(t - u) \\ &= \frac{-1}{\omega} \tilde{f}(\omega). \end{aligned} \quad (156)$$

Note that $\lim_{t \rightarrow \pm\infty} \left(\int du f(u) \text{sign}(t - u) \right) = 0$, so the contributions to the integration by parts from the upper and lower limits of integration vanish. $\square$

Thus, given any function $f(t)$ which decays as $|f(t)| \leq C \exp(-t^\alpha)$, for some $C, \alpha > 0$, we can find a filter function $F(t)$ which decays as $C \exp(-t^\alpha)$, for some other C . Note that given any even function $g(t)$ which has the Fourier transform with the property that $\tilde{g}(\omega) = 1$ for $\omega = 0$, $\tilde{g}(\omega) = 0$ for $|\omega| \geq 1$, we can define

$$f(t) = \delta(t) - g(t), \quad (157)$$

where $\delta(t)$ is the Dirac δ -function (since we convolve $f(u)$ against $\text{sign}(t - u)$, the resulting $F(t)$ is a function, rather than a distribution).

In the classic paper[19], it is shown how to construct such functions $g(t)$ such that

$$|g(t)| \leq \mathcal{O}(\exp(-|t|\epsilon(|t|))), \quad (158)$$

for *any* monotonically decreasing positive function $\epsilon(y)$ such that

$$\int_1^\infty \frac{\epsilon(y)}{y} dy \quad (159)$$

is convergent. For example, such a function $\epsilon(y)$ may be chosen to be

$$\epsilon(y) = 1/\log(2 + y)^2. \quad (160)$$

Thus, our function $g(t)$ has so-called “subexponential decay”[23]. A function $f(t)$ is defined to have subexponential decay if, for any $\alpha < 1$, $|f(t)| \leq C_\alpha \exp(-t^\alpha)$, for some C_α which depends on α . Thus,

Corollary 7. *There exist odd functions $F(t)$ with subexponential decay and with $\tilde{F}(\omega) = -1/\omega$ for $|\omega| \geq 1$. In fact, the resulting function $F(t)$ from the given $\epsilon(y)$ obeys*

$$|F(t)| \leq \mathcal{O}(\log(2 + |t|)^2 \exp(-|t|/\log(2 + |t|)^2)). \quad (161)$$

Below Eq. (185), we list even faster possible asymptotic decay.

Decay of Quasi-Adiabatic Continuation Operator

Given the rapid decay of $F(t)$ with t , we have a Lieb-Robinson bound for quasi-adiabatic continuation using this operator, as we now show. Assume a system has a spectral gap γ , and that $H_s = \sum_Z H_s(Z)$, with $H_s(Z)$ supported on sets Z of diameter at most R . Define a quasi-adiabatic evolution operator by

$$\mathcal{D}_s = \sum_Z \mathcal{D}_s^Z, \quad (162)$$

where

$$i\mathcal{D}_s^Z = \int dt F(\gamma t) \exp(iH_s t) \left(\partial_s H_s(Z) \right) \exp(-iH_s t). \quad (163)$$

If a Hamiltonian H_s has a spectral gap γ and a ground state $\Psi_0(s)$, then by construction

$$\partial_s \Psi_0(s) = i\mathcal{D}_s \Psi_0(s). \quad (164)$$

We now consider the decay properties of $i\mathcal{D}_s^Z$. Let O be an operator supported on a set which is distance at least l from Z . Then, using the Lieb-Robinson bound and a triangle inequality

$$\begin{aligned} \|[O, \mathcal{D}_s^Z]\| &\leq \int dt |F(\gamma t)| \|[O, \exp(iH_s t) \left(\partial_s H_s(Z) \right) \exp(-iH_s t)]\| \\ &\leq \left(\int_{|t| \leq l/v_{LR}} dt |F(\gamma t)| g(l) + 2 \int_{|t| \geq l/v_{LR}} dt |F(\gamma t)| \right) \times \|\partial_s H_s(Z)\| \|O\| \\ &\leq \check{E}(l) \|\partial_s H_s(Z)\| \|O\|, \end{aligned} \quad (165)$$

where we define

$$\check{E}(l) \equiv \frac{1}{\gamma} \left(\int du |F(t)| g(l) + 2 \int_{u \geq l\gamma/v_{LR}} |F(u)| \right), \quad (166)$$

where we used the change of variables, $u = \gamma t$. We define, for use later, $\check{E}(0) = 1$.

Define $b_l(Z)$ to be the set of sites within distance l of Z . Define an approximation to $\mathcal{D}_s^Z$ which is supported on $b_l(Z)$ by

$$\mathcal{D}_s^{Z,l} = \int dU U^\dagger \mathcal{D}_s^Z U, \quad (167)$$

where the integral ranges over unitaries U which are supported on the complement of $b_l(Z)$ with the Haar measure. Using the commutator estimate above, we can estimate the difference $\|U^\dagger \mathcal{D}_s^Z U - \mathcal{D}_s^Z\| \leq \| [U, \mathcal{D}_s^Z] \|$. So

$$\|\mathcal{D}_s^{Z,l} - \mathcal{D}_s^Z\| \leq \check{E}(l). \quad (168)$$

Define a sequence of operators $D_s(Z, j)$ by

$$D_s(Z, 0) = \mathcal{D}_s^{Z,0}, \quad (169)$$

for $j = 0$ and by

$$D_s(Z, j) = \mathcal{D}_s^{Z,j} - \mathcal{D}_s^{Z,j-1}, \quad (170)$$

for $j > 0$. We have the bound for $j > 0$, that $\|D_s(Z, j)\| \leq 2\check{E}(l)$. Thus, since

$$\mathcal{D}_s = \sum_{Z,j} D_s(Z, j), \quad (171)$$

we have decomposed $\mathcal{D}_s$ as a sum of operators on sets of increasing size and decreasing norm as follows.

For definiteness, let us assume that the initial Hamiltonian H has the property that the sets Z are all given by balls of radius $R/2$ about sets i (let R be even for simplicity). So, we write $H_Z = H_i$, where $Z = b_{r/2}(\{i\})$, and $\{i\}$ is the set containing just site i . Then,

Lemma 15. *For the given function $F(t)$,*

$$\mathcal{D}_s = \sum_{i \in \Lambda} \sum_{j \geq R/2} D_s(i, j), \quad (172)$$

where the sum is over sites i in the lattice Λ , and where $D_s(i, j)$ is an operator supported on $b_j(\{i\})$ and

$$\|D_s(i, j)\| \leq 2\check{E}(l - R/2) \|\partial_s H_Z(s)\|. \quad (173)$$

If a set $Y = b_j(\{i\})$, then we define $D_s(Y) = D_s(i, j)$. It is also worth bounding this as:

Lemma 16. *For any pair of sites i, j ,*

$$\sum_{Y \ni i, j} \|D_s(Y)\| \leq K(\text{dist}(i, j)), \quad (174)$$

where

$$K(l) \leq J' \sum_{m \in \Lambda} \sum_{k \geq \max(\text{dist}(i, m), \text{dist}(j, m))} \check{E}(k). \quad (175)$$

where we define

$$J' = \max_Z (\|\partial_s H_Z(s)\|). \quad (176)$$

We are now ready to derive the Lieb-Robinson bounds for evolution under $\mathcal{D}_s$. Define a unitary U_s corresponding to evolution with $\mathcal{D}_s$ by

$$U_s = \mathcal{S}' \exp\{i \int_0^s ds' \mathcal{D}_{s'}\}. \quad (177)$$

Let O_A be any operator supported on set A , and let O_B be an operator supported on set B , where B is the set of sites which are distance at least l from set A . We wish to bound

$$\|[U_s O_A U_s^\dagger, O_B]\|. \quad (178)$$

If a set $Y = b_j(\{i\})$, we will write $D_s(Y) = D_s(i, j)$ to save notation in what follows. We use the series expansion first derived in [3]:

$$\begin{aligned} \|[U_s O_A U_s^\dagger, O_B]\| &\leq 2(2|s|) \sum_{Y: Y \cap A \neq \emptyset, Y \cap B \neq \emptyset} \|D_s(Y)\| \\ &+ 2 \frac{(2|s|)^2}{2!} \sum_{Y_1, Y_2: Y_1 \cap A \neq \emptyset, Y_1 \cap Y_2 \neq \emptyset, Y_2 \cap B \neq \emptyset} \|D_s(Y_1)\| \|D_s(Y_2)\| \\ &+ 2 \frac{(2|s|)^3}{3!} \sum_{Y_1, Y_2, Y_3: Y_1 \cap A \neq \emptyset, Y_1 \cap Y_2 \neq \emptyset, Y_2 \cap Y_3 \neq \emptyset, Y_3 \cap B \neq \emptyset} \|D_s(Y_1)\| \|D_s(Y_2)\| \|D_s(Y_3)\| \\ &+ \dots \end{aligned} \quad (179)$$

We may bound this as follows:

$$\|[U_s O_A U_s^\dagger, O_B]\| \leq \sum_{i \in A} \sum_{j \in BG(i, j)}, \quad (180)$$

where $G(i, j)$ is defined by

$$\begin{aligned} &2(2|s|) \sum_{Y: i \in Y, j \in Y} \|D_s(Y)\| \\ &+ 2 \frac{(2|s|)^2}{2!} \sum_{Y_1, Y_2: i \in Y_1, Y_1 \cap Y_2 \neq \emptyset, j \in Y_2} \|D_s(Y_1)\| \|D_s(Y_2)\| \\ &+ 2 \frac{(2|s|)^3}{3!} \sum_{Y_1, Y_2, Y_3: i \in Y_1, Y_1 \cap Y_2 \neq \emptyset, Y_2 \cap Y_3 \neq \emptyset, j \in Y_3} \|D_s(Y_1)\| \|D_s(Y_2)\| \|D_s(Y_3)\| \\ &+ \dots \end{aligned} \quad (181)$$

We define

Definition 12. A function $K(l)$ is **reproducing** for a given lattice Λ if, for any pair of sites i, j we have

$$\sum_m K(\text{dist}(i, m)) K(\text{dist}(m, j)) \leq \lambda K(\text{dist}(i, j)), \quad (182)$$

for some constant λ .

For a square lattice in D dimensions and a shortest-path metric, a powerlaw $K(l) \sim l^{-\alpha}$ is reproducing for sufficiently large α . An exponential decay is *not* reproducing. However an exponential multiplying a sufficiently fast decaying power is. Using this definition and lemma (16) and Eq. (181), we arrive at the bound for a reproducing $K(l)$ that

$$\begin{aligned} G(i, j) &\leq 2K(\text{dist}(i, j))(2|s| + \frac{(2|s|)^2}{2!} \lambda + \frac{(2|s|)^3}{3!} \lambda^2 + \dots) \\ &\leq 2K(\text{dist}(i, j)) \frac{\exp(2\lambda|s|) - 1}{\lambda}. \end{aligned} \quad (183)$$

Now, we consider a specific case. In order to maintain generality in our choice of $F(t)$, we want one more definition.

Definition 13. A function $f(x)$ is of **decay class** $g(x)$ if

$$f(x) \leq c_1 g(c_2 x) \quad (184)$$

for all $x \geq 0$, for some constants c_1, c_2 .

In some cases we will specify the constants.

Consider a function $g(t)$ defined to have $|g(t)| \leq \mathcal{O}(\exp(-|t|\epsilon(|t|)))$, as constructed in [19]. Suppose $\epsilon(t)$ is any one of the following functions:

$$\frac{C}{\log(t)^2}, \frac{C}{\log(t) \log(\log(t))^2}, \frac{C}{\log(t) \log(\log(t)) \log(\log(\log(t)))^2}, \dots \quad (185)$$

From any such function, in the first section of the appendix we succeed in constructing a function $F(t)$ which is of decay class g . One may note that Eq. (161) has the extra factor $\log(2 + |t|)^2$ multiplying the decay of $F(t)$, but this is still asymptotically bounded by $\mathcal{O}(\exp(-c_2|t|/\log(2 + |t|)^2))$, for any $c_2 < 1$, so indeed $F(t)$ is of decay class $g(t)$.

We now restrict to finite dimensional lattices, so that the number of sites within distance l of any site grows at most polynomially with l . Then, we find that the function $\tilde{E}$ is also of decay class g . However, here it is important to specify the constants: the constant c_1 is proportional to $1/\gamma$, while the constant c_2 is proportional to γ/v_{LR} . The function K is of decay class $\tilde{E}$ with constants c_1, c_2 that depend on the dimension: the number of sites m in the sum in Eq. (16) will be dimension-dependent. We are not interested in these dimension dependent constants, but only in the constants that depend on γ . Note that K is of decay class g with c_1 proportional to J'/γ and c_2 proportional to γ/v_{LR} .

The functions K which arise from these functions g decay faster than $1/x^\alpha$ for any power α . So, for any $\alpha > 0$, for any $c_2 < 1$, $K(x)$ can be upper bounded by

$$K(x) \leq K'(x)/x^\alpha, \quad (186)$$

where $K'(x) = c_1 K(c_2 x)$ for some c_1 . Note that for sufficiently large α such functions K' are reproducing, and indeed one can pick $\lambda \leq C(J'/\gamma)$, for a dimension-dependent constant C of order unity. Also, K' is of decay class K . Define

$$G(l) = \max_{i,j}^{\text{dist}(i,j)=l} G(i,j), \quad (187)$$

so that $G(l)$ is an upper bound on $G(i,j)$ if $\text{dist}(i,j) = l$. Then,

Lemma 17. *For any of the functions $g(t)$ arising from ϵ in Eq. (185), the corresponding $G(l)$ is bounded by $\exp(C|s|J'/\gamma) - 1$ times $c_1 g(c_2 l \gamma / v_{LR})$, for some constant c_1, c_2 which are dimension dependent, but do not depend on γ or v_{LR} , and*

Similarly, in any finite dimensional lattice, after we sum over sites i, j we find that

Lemma 18. *For any of the functions $g(t)$ arising from ϵ in Eq. (185), the commutator $\|[U_s O_A U_s^\dagger, O_B]\|$ is bounded by $|A|$ times by $\exp(C|s|J'/\gamma) - 1$ times $c'_1 g(c'_2 l \gamma / v_{LR})$, for some constants c'_1, c'_2 which are dimension dependent, but do not depend on γ or v_{LR} .*

Optimization

In the next section, we will apply this lemma (18) to specific problems, where the error estimates depend upon the error in lemma (18) for l of order the system size L . Hence, we will find errors that decay with system size L similarly to the decay of $g(t)$ with t . In this section, we discuss optimizing these error estimates in a little more detail; the reader may prefer to skip this until later. The reader will perhaps realize that instead of choosing a function, such a $\exp(-|t|/\log^2(t))$, we could easily have chosen the function $\exp(-2|t|/\log^2(t))$ or indeed $\exp(-C|t|/\log^2(t))$ for any constant C . One may then start to get optimistic: if, for example, we prove that a certain error decays as $\exp(-1000L/\log^2(L))$, surely this is much better than proving that it decays only as $\exp(-L/\log^2(L))$. Of course, the trouble is the constant in front that we have not written: all the of the bounds on the decay of $g(t)$ are up to a constant in front, and by choosing a $g(t)$ which decays asymptotically as $\mathcal{O}(\exp(-1000|t|/\log^2(t)))$, we will find a much worse constant than if we had chosen $g(t)$ to decay only as $\mathcal{O}(\exp(-|t|/\log^2(t)))$. In fact, one will find that one gains only for very large t , and hence, for very large L .

The next possibility one may consider is: suppose, for definiteness, we choose $g(t)$ to decay as $\exp(-C|t|/\log^2(t))$ for a constant C . How can we optimize the constant C to obtain the best decay for a given system size L ? After all, perhaps if L is large one should choose a large constant C in defining $g(t)$, while for smaller L perhaps a smaller constant is better. However, as soon as one starts trying to optimize over constants, one should also try to optimize over functions. In order to obtain the best possible bounds, one would like to be able to consider all possible $g(t)$ for a given L . Thus, the problem which one would really like to solve is: for a given distance L , and a given dimension D , what function $g(t)$ will minimize the quantity $\exp(C|s|J'/\gamma) - 1$ times $c'_1 g(c'_2 L \gamma / v_{LR})$ in lemma (18) for $|s|$ of order unity? In particular, how does the minimum over $g(t)$ of this quantity behave for large L ? It should be clear that the term $\exp(C|s|J'/\gamma) - 1$ is important. While $|s|$ is of order unity, if C becomes large (for example, L -dependent) then this term will become large.

Applications

These operators immediately simplify and tighten several results. For example, [21, 22] rely on quasi-adiabatic continuation operators; using the operator here, the superpolynomial decay of the ground state splitting in those papers can be tightened to subexponential.

Further, these operators can be directly inserted into the proof in [8]. This greatly simplifies the construction of the quasi-adiabatic evolution operator. Further, one immediately finds that

Theorem 4. *Let $g(t) = \exp(-t\epsilon(t))$, where $\epsilon(t)$ is any function in Eq. (185). For Hamiltonians on a torus, as considered in [8], for fixed $R, J/\gamma$, the Hall conductance is quantized to an integer up to an error which is bounded by a function $e(L)$, where e is of decay class g .*
